The lipophilicity,  $\log P_{\text{TLC}}$ , of membrane components as determined by thin-layer chromatography is of the utmost relevance to the lifetime of liquid-membrane sensors. Since blood serum and whole blood are much more lipophilic than a purely aqueous solution they are much more efficient extractants for membrane components. The lifetime decreases by a factor of  $10^{-2.5}$  for direct measurements. Hence, much higher lipophilicities of host molecules and additives are required when membranes have to be contacted with these media. The required lipophilicity,  $\log P_{\text{TLC}}$ , of neutral carriers incorporated in ion-selective liquid membranes with a thickness of

$\sim 200 \mu\text{m}$  and a minimum lifetime of 720 h of contact to whole blood or plasma is  $> 11.3$ . For plasticizers the required  $\log P_{\text{TLC}}$  is  $> 14.3$ . Covalent binding of membrane components increasing the lifetime of sensors can be used only in a few cases.

### Calibration, Standardization, and Comparisons with Definitive or Reference Procedures

Ion-selective electrodes used in whole blood or undiluted plasma or serum respond to the electrochemical activity of the ion. At the high ionic strengths of  $I \approx 0.16 \text{ mol l}^{-1}$  encountered in these biological samples, the molality  $m_i$  can no longer be substituted for active molality  $\tilde{m}_i$ . Free ion molality  $m_i$  may be converted to the active molality  $\tilde{m}_i$  by multiplying with the molal activity coefficient  $\gamma_i$ :

$$\tilde{m}_i = m_i \cdot \gamma_i \quad \text{with } \gamma_i \neq 1 \quad [4]$$

By definition the active molality is related to the relative molal activity  $a_i$  by dividing  $\tilde{m}_i$  by the unit

<sup>a</sup> Calculations are based on active molality of ions as far as available (sodium, potassium, and chloride, especially).

<sup>b</sup> Calculations are based on active molalities derived from total substance concentrations, assuming an ionic strength of 0.16 mol l<sup>−1</sup>.

<sup>c</sup> Without: activity of the interfering ion = upper limit of reference range; activity of the primary ion = lower limit of reference range.

<sup>d</sup> With: activity difference of the interfering ion between mean value and the limit (upper or lower) of the reference range which results in the higher difference; activity of the primary ion = lower limit of reference range.

<sup>e</sup> SCN<sup>−</sup> as interfering ion is supposed to be at the maximum level for a smoker which is 0.15 mmol l<sup>−1</sup>.

Measurements in the specimen directly are differentiated from measurements in a 1 + 19 diluted sample. Data are calculated for an assay without calibration of the activities of the ion background as well as with calibration of a mean physiological background (2% complexation for Na<sup>+</sup>, but no complexation of further singly charged ions is assumed).

molality (1 mol kg<sup>−1</sup>):

$$a_i = \tilde{m}_i / (\text{mol kg}^{-1}) \quad [5]$$

Concomitantly the molality of free ions  $m_i$  differs from the total molality of the ion I,  $m_{i,\text{tot}}$ , by the association of the ions 'i' to organic and inorganic anions and cations ( $L_j$ ), respectively, and their molal concentration  $m_{Lj}$ . The degree of complexation is related to the chemical specification of an analyte ion and is higher for multiply charged ions and transition metals. It is denoted by the association constant  $K_{\text{ass}}$ :

$$m_{i,\text{tot}} = m_i + m_i \cdot \sum_{j=1}^n (K_{\text{ass},j} \cdot m_{Lj}) \quad [6]$$

Analytical systems that measure substance concentrations in moles per liter of plasma, e.g., atomic absorption spectrometry (AAS) and flame atomic emission spectrometry (FAES), coexist with determinations of relative ion activity in undiluted and diluted samples. In consequence a system of computing and reporting results of sodium and potassium ions was proposed by the International Federation of Clinical Chemistry (IFCC) to convert the results of direct ISE assays to FAES/AAS and vice versa.

The system reports on an adjustment factor by which the measured relative molal activity and the molality of the analyte ion I is related to the total substance concentration  $c_{i,\text{tot}}$ . The system is based on

the assumption of a standard plasma specimen defined as having a mass concentration of water in plasma of  $0.93 \text{ kg l}^{-1}$ , a hydrogencarbonate concentration of  $24 \text{ mmol l}^{-1}$ , and pH 7.4. For sodium ions the complexed fraction ( $\sum_{j=1}^n K_{\text{ass}j} \cdot m_{\text{L}j}$ ) is assumed to be 2%.

Based on these assumptions the total substance concentration of the ion I may be converted to the total molality of the analyte ion by dividing by the mass concentration of plasma water:

$$m_{i,\text{tot}} = c_{i,\text{tot}} / \rho_{\text{H}_2\text{O};\text{P}} \quad (\text{mol kg}^{-1}) \quad [7]$$

Hence, by the following completed equation the total substance concentration of I in moles per liter of plasma is related to the relative activity measured by ISEs:

$$c_{i,\text{tot}} = a_i \cdot \rho_{\text{H}_2\text{O};\text{P}} \cdot \left( 1 + \sum_{j=1}^n K_{\text{ass}j} \cdot m_{\text{L}j} \right) \cdot (1 \text{ mol kg}^{-1}) / \gamma_i \quad [8]$$

Although the system is based on molal units by definition (International Union of Pure and Applied Chemistry and the IFCC), the results are strongly related to the temperature since the slope of the ISE response function increases with increasing temperature. Routinely all measurements are made at  $37^\circ\text{C}$ .

To estimate the mass concentration of water in plasma a volume displacement effect by proteins and lipids has to be taken into account and is integrated in the mass concentration factor for standard plasma specimens. The correction factor for the mean specific volume of proteins is assumed to be 0.73 and 1.03 for lipids, respectively:

$$\rho_{\text{H}_2\text{O};\text{P}} = 0.991 - 0.73c_{\text{protein}} - 1.03c_{\text{lipid}} \quad (\text{kg l}^{-1}) \quad [9]$$

A theoretically predicted positive bias of 6.7% for direct potentiometry (total ion molality in plasma water) versus indirect assay (total ion concentration in the whole sample volume) is generally accepted for normal situations and is compensated by calibration.

Ion-selective electrodes offer an observable value for the biologically relevant parameter: the ion's active molality in the aqueous phase of the biological specimen directly. This might be a challenge for elements that are associated by 30–50% to different anions, e.g., magnesium and calcium. For alkaline and alkaline-earth metal cations the Debye–Hückel formalism allows a fair approximation of the mean activity coefficient  $\gamma_{i\pm}$  as measured for an ion and its counterion in a calibration solution. The notation of

the basic theory has varied during history and was adapted for higher accuracy of biological measurements and for estimations of single ion activities. The aim of these efforts was an optimal approximation of the true molal activity coefficients in plasma or whole blood for the calculation of ion concentrations based on the ion's active molality measurements. Factors for standard plasma estimated by the Debye–Hückel formalism at  $37^\circ\text{C}$  are given in Table 1. However, particularly in the most relevant cases when hyperhydration, dehydration, and strong changes in osmolality, ionic strength, and in the ion background activities occur, ion concentration levels do not correlate with measured active ion molality and computations based on fixed factors are useless. Hence, the outstanding information content of the molal ion activity parameter for biological measurements is lost through correlation with total ion concentrations.

No standard reference material and procedure is actually available for molal ion activity assays. Calibration of the electrode is required. The calibration solution should match the mean sample composition as closely as possible. Addition of albumin to the calibration standard does not guarantee high accuracy of the results due to a shift of the assay standard potential that is different for plasma, serum, and albumin. Reports on comparisons of clinical analyzers show that interinstrumental deviations may be considerable. Recommendations for calibration and standardization by the IFCC Committee on Electrolytes and Blood Gases are in preparation.

Electrolyte total concentrations are generally evaluated in samples diluted by an ionic strength and pH buffer in the so-called indirect method. Due to the known standardized background, calibration and calculation of the active ion molality based on the Debye–Hückel formalism are allowable. Differences between indirect ISE assays and FAES or AAS are obvious and amount to  $\sim 3\text{--}4\%$  higher results for ISEs. They are most probably related to the volumetric dilution and the volume displacement effect by macromolecules relevant even in diluted samples.

Whenever the comparability between the two methods is impaired by the effects reported, the composition of whole blood is still relatively stable and predictable. The discussions of what should be measured and what should be reported are due to the extremely high quality requirements for most analytes. The evaluation of standard specimens for ion active molality determinations in a symmetric cell arrangement may be considered for future developments.

## Interpretation and Clinical Decision-Making

The comprehensive and critical examination of analytical and clinical decision-making is discussed and reported in numerous papers and volumes. Fundamentally, the evaluation of the efficiency of analytical tests has to be distinguished from the evaluation of procedures for medical decision-making. However, data evaluation in clinical chemistry is based on a stepwise process that starts with the value measured by the analytical instrument. The instrumental output is most frequently represented by a metric signal on a continuous scale. By calibration and standardization this value is transformed to a reliable analytical result. In contrast, clinicians intuitively regard an assay in terms of its ability to discriminate differences between two values. The medical validation reduces the full information to a binary decision that is coded 'healthy' or 'ill' as well as 'continue therapy' or 'change therapy' in most cases. The cutoff value for decisions is denoted as a reference value specifically evaluated for the population involved. Assuming that analytical problems such as drifts, inaccuracies induced by the biological matrix and interfering ions have been minimized, the analytical performance is monitored in terms of the long-term reproducibility denoted by the coefficient of variation  $cv_a$ . However, the discriminatory power of an assay in any biological setting point involves the analytical and the biological variation ( $cv_b$ ) assuming near Gaussian distributions for both. The difference between two single values is statistically significant (2.5% level for the one-tailed normal deviate with  $Z = 1.96$ ) provided that the difference between ion concentrations  $\Delta c_{i, \text{tot}}$  or active ion molalities,  $\Delta \bar{m}_i$  exceeds  $2.8 \times$  the total variation  $((cv_b^2 + cv_a^2)^{1/2})$  within the considered range of values. Since the intraindividual variation ( $cv_{b, \text{intra}}$ ) is smaller than the interindividual variation ( $cv_{b, \text{inter}}$ ), with few exceptions, individual longitudinal studies are considered more reliable for interpretation (see Table 1).

## Applications

### Microelectrodes

The miniaturization of ISEs allows the possibility of local measurements of ion activities in tissues, on surfaces, and through catheters. However, the diameter of the tip of microelectrodes is in many cases too large for *in vivo* measurements. A rule of thumb is that this diameter should be  $< 1/20$  of the larger extension of a cell. In the range  $< 1 \mu\text{m}$  a very low ion-exchange current of the primary ion as well as leaking currents of glass electrodes limit the selectivity and the response of microelectrodes. Potassium, calcium, and magnesium pH-selective microelectrodes were successfully applied for measurements in the microenvironment.

### Nonsymmetrical Ion Sensors and Solid-State Electrodes

The general trend to miniaturize chemical sensors and to make them cheap and easier for handling has led to the development of potentiometric sensors with solid internal contact. This class of sensors includes different types of solid-state electrodes, solid-state contact, and coated wire electrodes as well as ion-selective field-effect transistors (FETs).

Solid-state sensors for chloride, iodide, and fluoride are based on the solubility product of silver chloride or silver iodide particles in silicone rubber and a doped lanthanum fluoride single crystal, respectively. The fluoride-selective electrode was applied for the analysis of urine and bone tissue of people exposed to industrial sources as well as for control of therapeutic fluoride application for osteoporosis, whereas the chloride-selective sensor was applied to the analysis of sweat for the diagnosis of cystic fibrosis. In solid-state contact electrodes the solvent polymeric membrane is directly contacted to the solid field transducing element, although the reference electrode is separated from the ion-selective sensing pad.

In ion-selective field-effect transistors (ISFETs) a solvent polymeric membrane is directly contacted with the FET and the reference electrode is integrated in the sensor. A sandwich structure built on semiconducting layers operates as an electrochemical potentiometric cell. With this approach the high impedance signal from the highly resistive miniaturized electrode can be amplified *in situ* and ideally only one capacitive interface in the measuring circuit has to be respected. Concomitantly the key issue is this single interface between the ion-selective membrane and the contacted gate insulator. A prerequisite is a conductivity of the membrane due to the permselectivity and the transition of the analyte species only, related to a minimum thickness of the membrane in the range of  $> 50 \mu\text{m}$  at least. The gas permeability of the membrane ( $\text{CO}_2$ ) is often responsible for unpredicted deviations. Light sensitivity and drift problems in ISFET structures are common. Several attempts have been made to modify the ISFET response by surface modifications and by immobilizing bioselective compounds such as enzymes and antibodies. Some of the most critical drawbacks have been overcome and applications of semiconducting layers for on-line blood electrolyte monitoring by ChemFET arrays have been demonstrated.

### Automation

Crucial factors affecting the use of analytical tools in the clinic are speed and reproducibility. A clear advantage of automated systems is the feasibility of the compensation of inaccuracies due to the properties

of the biological sample by the continuously updated calibration procedure, the chemometric compensation of the effects of interfering ions within the dynamic range, and the adjustment of the liquid junction potential by calibration and computing procedures. A number of instruments for measurements in whole blood, serum, or plasma directly with ISE arrays are available. The core of the analytical flow-through system is a thermostatted and in most cases completely transparent measuring chamber ( $T = 310\text{ K} \pm 0.1$ ). The required sample volume normally ranges from 50 to 300  $\mu\text{L}$ .

In most large automated biochemistry analyzers electrode concentrations are evaluated in the diluted sample by ISEs, by the so-called indirect method. A special compartment for the determination of sodium, potassium, and chloride is integrated. The ISEs have replaced flame photometry as well as coulometry to a large extent. However, the compatibility as well as interpretability of the results is problematic in many cases (see above). Since the ion-selective assays strictly respond to molal single-ion activities in the aqueous phase, the comparability to direct measurements is weak. A volume displacement effect by lipids and proteins even affects the accuracy and comparability in diluted samples with buffered ionic strength.

## Introduction

Ion-selective electrodes (ISEs) offer several possibilities in food analysis, mainly for the determination of

microcomponents such as nutrients, contaminants of various origin, and chemicals added during food processing. To obtain meaningful analytical results special protocols for sample preparation and measurement must be carefully followed. The determination of sodium, potassium, calcium, ammonium, fluoride, chloride, and nitrate, as well as the measurement of pH, are the most common applications of ISEs in foodstuffs analysis.

of the biological sample by the continuously updated calibration procedure, the chemometric compensation of the effects of interfering ions within the dynamic range, and the adjustment of the liquid junction potential by calibration and computing procedures. A number of instruments for measurements in whole blood, serum, or plasma directly with ISE arrays are available. The core of the analytical flow-through system is a thermostatted and in most cases completely transparent measuring chamber ( $T = 310\text{ K} \pm 0.1$ ). The required sample volume normally ranges from 50 to 300  $\mu\text{L}$ .

In most large automated biochemistry analyzers electrode concentrations are evaluated in the diluted sample by ISEs, by the so-called indirect method. A special compartment for the determination of sodium, potassium, and chloride is integrated. The ISEs have replaced flame photometry as well as coulometry to a large extent. However, the compatibility as well as interpretability of the results is problematic in many cases (see above). Since the ion-selective assays strictly respond to molal single-ion activities in the aqueous phase, the comparability to direct measurements is weak. A volume displacement effect by lipids and proteins even affects the accuracy and comparability in diluted samples with buffered ionic strength.

## Introduction

Ion-selective electrodes (ISEs) offer several possibilities in food analysis, mainly for the determination of

microcomponents such as nutrients, contaminants of various origin, and chemicals added during food processing. To obtain meaningful analytical results special protocols for sample preparation and measurement must be carefully followed. The determination of sodium, potassium, calcium, ammonium, fluoride, chloride, and nitrate, as well as the measurement of pH, are the most common applications of ISEs in foodstuffs analysis.

## Characteristics of Potentiometric Sensors in Food Analysis

The analysis of foodstuffs using ISEs must take into account the special nature of the sample, the characteristics of ISEs, and the conditions of measurements. In contrast to most analytical techniques, in potentiometric measurements the analytical signal is directly correlated to the activity of the sensed species. This could be of advantage in food analysis as the bioavailability of a species is closely related to the activity of the ion. However, measuring the activity of analytes in real samples requires the fulfillment of special conditions that are rarely attained in practical analysis. The activity of the analyte ion depends on the characteristics of the medium, e.g., its electric permittivity, temperature, and ionic composition, the latter being expressed in dilute solutions by the value of the ionic strength. The presence of nonaqueous solvents also influences the activity/concentration relationship. Therefore for samples that are dilute aqueous solutions alone a potentiometric measurement may give a relatively reasonable evaluation of the activity. In the case of real food samples, we rarely have such ideal situations. In most cases samples, both liquid and solid, need pretreatment, such as dissolution, dilution, extraction of the analyte, or separation of interferents. After such a treatment the only information that may be gained from the potentiometric measurement is the concentration of the analyte.

The correct interpretation of the relation between the activity and the concentration requires a proper choice of experimental conditions and a careful interpretation of the results. The most common procedure involves the use of an ionic strength adjustment solution (buffer). It consists of an inert salt at constant concentration that does not interact with the analyte (e.g.,  $\text{KNO}_3$ ), providing a solution of constant ionic strength, not influenced by small changes in the composition of the sample solution. Usually the other components have additional functions. For example, in total fluoride determination, metal ions, such as  $\text{Al}^{3+}$  or  $\text{Fe}^{3+}$ , which bind fluoride ions, should be complexed with cyclohexane-1,2-diamine- $N,N,N',N'$ -tetraacetic acid to liberate fluoride ions. In determination of total calcium content, controlled complexation of the analyte by addition of iminodiacetic acid eliminates the effects caused by the presence of other weaker complexants of various strengths and concentrations. Usually such an ionic strength adjustment solution also contains a pH buffer, which provides the optimal pH value for the ISE used. Under conditions of constant ionic strength there exists an exact correlation

between the potential reading and the logarithm of concentration of the analyte ion according to the Nernst equation.

A very special situation exists in the case of pH measurements based on measurements made using glass electrodes or other membrane sensors selective to hydrogen ions. By definition, the pH value is directly related to the logarithm of the activity of the hydrogen ion in solution. This is determined by calibrating the meter with primary (or secondary) pH standard buffers. However, aqueous standards may be usable only under specific conditions. When measurements are carried out under conditions differing from these, as in the presence of ethanol, the result of the measurement has only a relative value, e.g., indicating whether the samples differ from one another. Good results, less dependent on the sample material, are obtained from differential pH measurements. The possibility of measuring pH potentiometrically with high precision, coupled with the high specificity of enzymatic reactions, permits the determination of a variety of analytes (urea, citric acid, reducing sugars, alkaline phosphatase, pesticides, etc.) in milk, wine, and other fluid samples, with no or little sample pretreatment.

In principle ISEs are sensitive only to free (hydrated) ions of the analyte and do not respond to various complexed species of the analyte. This property could be exploited in speciation analysis, distinguishing the free and bound analyte species. However, it must be remembered that most procedures of sample pretreatment, dilution, extraction, and addition of reagents, change the initial speciation, corresponding to the nontreated sample. Therefore, only when the species are kinetically inert and the sample pretreatment is carried out with special caution is there a possibility of analyte speciation. For example, calcium in milk is present as a free (hydrated) ion or in combination with proteins, lipids, or better molecular mass species. The evaluation of each of the species is the aim of speciation analysis. The task is relatively simple when the species investigated are inert, do not dissociate, or otherwise undergo decomposition during sample pretreatment. A similar problem is common in the analysis of other biological samples, e.g., in blood analysis, where even a 20-fold dilution results in nearly complete dissociation of calcium complexes with various ligands.

Potentiometric (as well as other electrochemical) measurements have an important advantage over optical measurements in that the color or opacity of the sample solution do not obscure the correct determination of the analyte. On the other hand, the functioning of the electrodes in the presence of colloids and suspensions may also produce erroneous

results. This is described as a suspension effect that is due to blocking the electrode surface or the porous plug connecting the reference electrode. This requires frequent checking of the proper functioning of the electrode system, or even using special electrode systems to avoid trouble. Measurements using flow systems often diminish such effects.

The main limitation of the use of ISEs in practical analysis is in the range of analyte determination and the selectivity of the electrodes. Most commercially available electrodes allow precise measurements of the analyte down to  $10^{-5}$ – $10^{-6}$  mol l<sup>-1</sup> concentrations. For some crystalline electrodes this may be shifted down by some orders of magnitude, but only in the case when the species measured remains in a labile equilibrium in an ion (e.g., metal ion) buffer. Obviously measurements in the lowest concentration range suffer all the difficulties typical for trace analysis (e.g., contamination), which may affect the determination. The concentration range of analyte that may be measured using ISEs is usually between  $10^{-2}$  and  $10^{-4}$  mol l<sup>-1</sup>, and the sample size and its subsequent dilutions should be adjusted to these conditions.

Several electrodes of differing selectivity are commercially available at present for measurements of most common ions. Preliminary information may be obtained on the basis of tabulated values of the selectivity coefficients; nevertheless, it must be remembered that their values depend on the method of determination, on the manner in which the electrodes are maintained, and on the life of the electrode. Therefore it is a good habit to check the selectivity under standard conditions. After long periods of use the selectivity of the electrode may also change, giving rise to erratic results. For reliable measurements the potentiometric selectivity coefficient should not be greater than  $10^{-2}$  for ions of the same charge and for comparable concentration levels of the analyte and interferent.

Quantification of the measurements made using ISEs can be carried out in different ways. The most common one is based on the calibration graph, prepared using standard calibrating solutions adjusted to the expected concentration range of the analyte, with a similar addition of the ionic strength adjustment solution. Another possibility is the known addition or analyte addition mode. These modes may often help eliminate possible interferences. For determination of larger concentrations, ISEs are often used as endpoint indicators in titrations. The acidity of foodstuffs is determined routinely using acid–base titration with a pH-sensitive electrode, glass electrodes being used most commonly as the indicator. It should be mentioned that titration gives the concentration of the analyte directly.

## Electrode Types and Measurement Systems

The analytical characteristics of ISEs are essentially independent of the electrode construction. The classical electrode design with an internal reference solution and electrode is still most commonly used for electrodes with crystalline membranes as well as for electrodes with a polymeric membrane with a neutral or charged carrier. Polymeric electrodes of the ‘coated wire’ type are simple, but over a long period their standard potential may shift, and they need frequent calibration. The use of an intermediate layer, e.g., based on conducting polymers, significantly improves their response. Miniaturized electrodes with micrometer-size sensor tips are becoming common, especially for extremely small sample sizes. However, this is not common in the case of food sample analysis. Electrodes constructed using ion-selective field effect transistors (ISFETs) and those produced using screen-printed or thin-film technology are gaining interest.

Multimembrane systems are another type of potentiometric sensor based on ISEs, wherein the ISE response is modified by an additional membrane of a different function. To this group of sensors belong gas-sensitive electrodes, with a hydrophobic membrane isolating the analyte from the complex sample medium. The chemical reaction of the gaseous analyte with a component of the solution surrounding the ISE membrane proper directly produces the species to be sensed by the electrode. In food analysis, electrodes used for sulfur dioxide or ammonia belong to this group of sensors.

The next group of multimembrane systems comprises membranes sensitized biologically using immobilized enzymes or microorganisms. Species that are directly sensed by an ISE are produced in the enzymatic reaction of the analyte. Examples of such sensors are those used for determination of urea in milk, based on immobilized urease and measurement of a pH change. An example of the application of bacteria strains is the use of immobilized recombinant *Escherichia coli* coupled with a pH electrode. Such electrodes have been used for determination of cephalosporins. When this bacterial strain is coupled with a CO<sub>2</sub> gas sensor, glutamic acid determination can be carried out.

Techniques based on micromachining technology are being increasingly exploited in the construction of commercially available sensor arrays, which find interesting applications in food analysis. The individual potentiometric sensors composing an array may be based on principles similar to those of classical potentiometric sensors. For practical

**Table 1** Examples of applications of sensor arrays – electronic tongue and electronic nose – in food analysis

<i>Samples</i>	<i>Type of sensor array</i>
Fortified feed	Enzymatic (lysine oxidase) sensor + seven solid state sensors for elimination of ionic interferences on determination of lysine
Apple varieties	ISFET sensor array for determination of $H^+$ , $K^+$ , $Na^+$ , and $Ca^{2+}$
Soft drinks	Eight cross-sensitive polymeric membranes on a screen-printed carbon paste electrode
Beers	Twelve cross-sensitive polymeric membranes on a chip
Coffee varieties	A sensor array of 30 sensors

reasons they are used in a miniaturized form, e.g., ISFETs or metal oxide semiconductor field effect transistors. In simpler systems they may permit the determination of individual components, with the elimination of interference due to cross-sensitivity of different sensors. Their unique and main advantages are the possibility of performing a qualitative analysis and recognition and discrimination of complex liquid and gaseous samples. These are based on the use of a sensor array composed of a number of nonselective sensors, together with mathematical signal processing methods based on artificial intelligence and pattern recognition, such as artificial neural networks. Such systems when used in analyses of liquid samples are termed electronic tongues, and in the case of gaseous samples they are called electronic noses. They have been applied e.g., for distinguishing beers and varieties of fruits or for detection of adulteration of foodstuffs, as shown in Table 1.

## Applications

In this section applications related to drinking water and mineral water are not discussed as they generally pose no special problems and such samples may be similarly treated as model solutions.

Sodium, potassium, calcium, ammonium, fluoride, chloride, and nitrate determinations and measurement of pH are among the applications of ISEs in foodstuffs analysis. Sodium and potassium determinations are two of the assays most easily performed using ISEs.

Sodium is usually present in the ionized form and in consequence in solutions to be measured as the free hydrated ion, often in high concentrations. Under these conditions, the method of analyte addition is the most preferred one. For example, an amount of analyzed sample containing from 2 to 200 mg of sodium should be dissolved or leached with 100 ml

of distilled water. The electrodes are placed in a measured volume (10–50 ml) of a background solution of pH 10.2, containing a known concentration of  $0.1\text{--}10\text{ mmol l}^{-1}$  sodium chloride and  $0.5\text{ mol l}^{-1}$  triethanolamine. After the potential stabilizes, a small volume, 0.1–1.0 ml, of the sample is added. The conditions are suitable for measurements when the potential change after the sample addition is in the range 6–20 mV. The concentration of sodium in the sample solution is calculated from the potential increase and the slope of the sodium electrode calibration curve. At low levels of sodium the results may be erroneous due to inevitable contamination with sodium.

When the sodium and potassium levels are lower, the multiple known addition method is preferred. An example is in the determination of sodium and potassium in wine. The presence of ethanol at a level of 10% can affect the performance of the solvent polymeric membrane electrode and change to some extent the selectivity of every type of electrode. Therefore a tenfold dilution of wine samples or an addition of a comparable amount of alcohol to the standards is recommended. Samples can be diluted with a triethanolamine solution that provides proper pH buffering. A wine sample can also be mixed with an ionic strength adjustment solution. Several additions of standard solution are made and the results are calculated using Gran's method. In the case of potassium determination the results may be seriously distorted when diffusion of potassium ions from the reference electrode is not prevented using a double junction bridge containing lithium acetate.

Determination of calcium is usually based on the total calcium content as differentiation between free and bound calcium is possible only when the initial liquid sample is measured directly and has not been modified by pH adjustment. The optimal pH range is usually in the range from 5 to 9. Calcium is often determined in milk and milk products. Usually a  $4\text{ mol l}^{-1}$  solution of KCl is added to the sample as an ionic strength adjustment solution. The potential readings are compared against a calibration curve. For determination of total calcium content the sample is ashed and the residue is dissolved in a small volume of dilute hydrochloric acid and passed through an ion exchange column to remove pyrophosphates and hydrated silicates. Then the resulting solution is diluted to have the calcium concentration in the optimal concentration range, adjusted for pH value and ionic strength. The potential is measured and compared against a calibration curve. Alternatively, the standard addition method can be used for both determinations.

Fluoride is important for dental health but in excess amounts is known to be toxic. The only interfering ion for a fluoride electrode is the hydroxide ion. The determination of the fluoride ion is not disturbed by the presence of most accompanying ions except those that complex fluoride ions, such as aluminum or iron. To eliminate such interferences the ionic strength adjustment solution usually contains acetic acid buffer of pH  $\sim 4.5$  and a ligand, such as polyaminopolyacetate or citrate, which should complex the interfering metal ions. As the fluoride level in foodstuffs is usually low, the only problem is preparation of the sample to match the concentration in the final solution with the optimal determination range. The total fluoride content is measured after digestion of the sample. This can include ashing, fusion, oxygen flask combustion, and hot acid digestion. The best procedures involve the use of closed systems where the sample is decomposed with concentrated nitric acid at 100–120°C. Under these conditions loss of fluoride from the sample is avoided. The best procedures use the multiple standard addition method for fluoride determination. In analysis of flour or milk the treatment of the samples with perchloric acid makes it possible to determine fluoride at a level below 0.4  $\mu\text{g per g}$ . The content of free fluoride may be determined with minimum sample handling and treatment in a liquid sample e.g., wine.

The chloride content in foodstuffs can be determined by titration with silver nitrate using either a chloride ISE (crystalline or positively charged site membrane) or a silver electrode as the indicator. Direct determination with ISEs is convenient for low chloride contents; however, both procedures are affected by the presence of bromide or iodide when their concentrations are significantly larger than that of chloride. In protein-rich samples some irregularities of electrode functioning are often observed. Interference from bromide and iodide as well as from protein adsorption can be avoided by boiling the blended and mixed sample with 0.1  $\text{mol l}^{-1}$  nitric acid. For complicated food matrices a microdiffusion cell technique has been used to simplify the sample. The food sample is digested with cold concentrated sulfuric acid, and the diffusion process is allowed to proceed for  $\sim 24$  h. Thus chloride is converted into hydrochloric acid, which is transported in the diffusion cell into the receiving reagent. Then the chloride content is directly determined in the receiving reagent by comparison of a chloride ISE potential with the calibration curve.

Determination of nitrate is in principle simple; however, there are several interferences, the main ones being chlorides and hydrogencarbonates. They

may be eliminated by the addition of an ionic strength adjustment solution that is composed of 0.01  $\text{mol l}^{-1}$  silver sulfate, 0.06  $\text{mol l}^{-1}$  potassium sulfate, and sulfuric acid to acidify the solution to a pH value less than 4. Determination in potatoes needs only blending of the sample and extraction with distilled water and addition of the ionic strength adjustment solution. Some disruption may occur when outflow of chloride from the reference electrode is not prevented.

A rather rare example indicating the possibility of speciation analysis is the determination of ionic copper, in the range from 20 to 90  $\mu\text{g l}^{-1}$  using a copper-selective electrode in a sample of wine when the total copper content is in the range from 0.10 to 1  $\text{mg l}^{-1}$ . The sample is modified very little by the addition of a 10% volume of 1  $\text{mol l}^{-1}$   $\text{KNO}_3$ , as should be done with standard solutions.

ISEs have been used for determination of food additives such as saccharin and cyclamate. The sensor used is based on a poly(vinyl chloride) membrane containing the analyte salt in a suitable ionic form as a positively charged site e.g., with an ammonium or basic dye cation. Such sensors are not commercially available but can be made easily in the laboratory.

Enzyme electrodes, having an immobilized enzyme or a microbial culture containing an enzyme, operate on the basis of catalytic activity with subsequent detection of the product of the enzymatic reaction. The outcome, depending on the reaction, is e.g., a product like ammonia or a pH change in the medium, which is sensed by a corresponding sensing element.

Sensors used for determination of pesticide (proprhex, paraoxon) residues in vegetables are enzymatic multimembrane devices whose functioning is based on the principle of inhibition of the activity of an enzyme such as acetylcholine esterase. This reaction is monitored by a pH sensor. The response of such biosensors to herbicides and pesticides opens a new area of testing possibilities in food analysis.

Among the more complicated procedures involving ISEs, one can mention the determination of nitrite using a procedure that combines the derivatization of nitrite by diazotization of sulfanilic acid and coupling with 1-naphthylamine. The product of this reaction is detected potentiometrically using an ion-pair electrode with a membrane containing the anion paired with a nickel-phenanthroline complex. Such a procedure has excellent selectivity and permits detection below the microgram per gram of nitrite level in meat. Another nontrivial procedure is based on stoichiometric oxidation of glycerine using an excess of periodate and determination of the excess oxidant using an  $\text{IO}_4^-$ -selective electrode.

**Table 2** Examples of applications of ISEs in food analysis

Analyte	Sample	Electrode type
Acetate (Ac)	Vinegar	Ac <sup>-</sup> positively charged site polymer electrode
Ammonium, ammonia	Tea, juices, wine, shrimps	NH <sub>4</sub> <sup>+</sup> neutral carrier polymer electrode NH <sub>3</sub> gas electrode
Aspartame	Processed food, dietary food	Enzyme aspartase + NH <sub>3</sub> gas electrode
Benzoate (Bz)	Beverages, juices	Bz <sup>-</sup> neutral carrier polymer electrode
Bromide	Alfalfa	Br <sup>-</sup> crystalline electrode
Calcium	Meat, sugar, milk, fruits, wine, seaweed	Ca <sup>2+</sup> neutral carrier polymer electrode
Carbon dioxide	Beverages, wine	CO <sub>2</sub> gas electrode
Chloride	Various foods, cheese, meat, fish, cakes, canned vegetables	Cl <sup>-</sup> crystalline electrode or Cl <sup>-</sup> positively charged site electrode
Copper	Wine	Cu <sup>2+</sup> crystalline electrode
Cyanide	Alcoholic beverages	HCN gas electrode
Cyclamate (Cy)	Processed food	Cy <sup>-</sup> positively charged site electrode
Fluoride	Grain, milk, beer, cheese, fish, fruits, vegetable, wine, tea	F <sup>-</sup> crystalline electrode
Glycerol, glycol	Spirits, wine	IO <sub>4</sub> <sup>-</sup> positively charged site electrode
Iodide	Milk	I <sup>-</sup> crystalline electrode
$\beta$ -Lactams	Fermentation broth, milk	Microbial <sup>a</sup> + pH sensor
Nitrate	Various foods, wine, meat, sugar, spinach, potato	NO <sub>3</sub> <sup>-</sup> positively charged site electrode.
Nitrite	Meat	NO <sub>2</sub> <sup>-</sup> derivative positively charged site electrode
pH	Fruit juices, meat, milk, milk products, vinegar, beverages	Glass electrode or H <sup>+</sup> neutral carrier polymer electrode
Potassium	Wine, fish	K <sup>+</sup> neutral carrier electrode
Propoxur	Lettuce, onions	Enzymatic (AChE <sup>b</sup> ) inhibition + pH electrode
Saccharin (Sac)	Dietary products	Sac <sup>-</sup> positively charged site electrode
Sodium	Soup stock, dried milk, infant formulations, canned food	Na <sup>+</sup> neutral carrier electrode Na <sup>+</sup> glass electrode
Sulfide	Wine, fruit, vegetable	Ag <sub>2</sub> S crystalline electrode
Sulfur dioxide	Wine, processed food	SO <sub>2</sub> gas electrode
Urea	Milk	Enzyme urease + NH <sub>3</sub> gas electrode Bacterial cell <sup>c</sup> + NH <sub>4</sub> <sup>+</sup> neutral carrier electrode

<sup>a</sup> Containing  $\beta$ -lactamase.<sup>b</sup> AChE, acetylcholine esterase.<sup>c</sup> Containing urease.

A selection of some procedures used in food analysis is presented in Table 2.

Another example in food analysis is the use of solid state copper and silver electrodes for evaluation of meat freshness. This is due to the change of putrescine and dimethyl sulfide, the concentration of which changes during meat putrefaction. Such applications indicate the variety of applications of ISEs in food control and analysis.

### Introduction

It would be difficult to underestimate the importance of the analysis of waters. It has long been recognized that the use of water for human consumption depended on its purity. More recently environmental considerations have led to recognition of the importance of water purity in preservation of the aquatic environment and food chains within it. Over the past few decades the importance of water quality has come to be appreciated in all of the applications to which water is put. The analyses that are required to ensure that the water is of the correct quality are numerous and legislative standards are in place for many of these analyses. Ion-selective electrodes play two kinds of role in water analysis, the first in those cases where the ion-selective electrode method is the most analytically suitable and the second where the ion-selective electrode is the most appropriate because of the dynamic real-time analytical capability of the ion-selective electrode which allows continuous monitoring of the water.

The requirements for monitoring water quality occur in several environmental situations, in the monitoring of river quality, in the analysis and control of potable water supplies, and in sewage treatment. In addition, the quality of water is important in many industrial situations, for example, for monitoring the quality of boiler feed water, in food production, and in pharmaceutical production. Ion-selective electrodes play an important role in many of these areas.

### Measurement Considerations in Using Ion-Selective Electrodes for Concentration Measurement in Waters

Ion-selective electrodes measure activities rather than concentrations. They require a buffer to maintain the

ionic strength constant so that concentrations may be used instead of activities. The ion-selective electrode measures the free ion, chemical interferences can occur as a result of, for example, complexation or protonation. The ion-selective electrode has a response to the ion of interest but also responds to other ions in the solution. The ion-selective electrode's response to the ion that it is designed for is greater than that to the other ions present. Whilst the term ion-selective electrode is used in this article in common with general terminology the term ion-sensitive electrode would be a preferable description of the electrode's response. The response of the electrode to concentration is logarithmic, rapid (less than 1 min to stabilize unless concentrations are very low or for some liquid ion-exchange electrodes), and temperature dependent. The electrodes are not ultra-sensitive and frequent calibration is required for all electrodes. The electrodes and their associated measurement equipment are small and readily portable.

The ion-selective electrodes will function satisfactorily, if the precautions suggested by the manufacturer are followed; however, faults can be readily identified in ion-selective electrode measurement systems. The response of the electrode should not be slow and the theoretical slope of the electrode potential against logarithm of concentration plot at 25°C should be  $(58 \pm 1)/n$  mV where  $n$  is the number of electrons in the electrode reaction. Slow response times and deviations of slope from the theoretical value can indicate electrode faults and in water analysis particularly in *in situ* or continuous monitoring this can be due to fouling of the electrode by contaminants in the solution. The contaminants can sometimes be removed and the electrode will then function normally. The response time in flowing systems has to be carefully investigated because a slow response time may simply be associated with the passage of solution through the system flow cell rather than an electrode fault. Drift in the potential value obtained from the electrode can be due to temperature variation or in some cases inadequate stirring or flow. Failure to obtain suitable readings on

Whilst the term ion-selective electrode is used in this article in common with general terminology the term ion-sensitive electrode would be a preferable description of the electrode's response. The response of the electrode to concentration is logarithmic, rapid (less than 1 min to stabilize unless concentrations are very low or for some liquid ion-exchange electrodes), and temperature dependent. The electrodes are not ultra-sensitive and frequent calibration is required for all electrodes. The electrodes and their associated measurement equipment are small and readily portable.

The ion-selective electrodes will function satisfactorily, if the precautions suggested by the manufacturer are followed; however, faults can be readily identified in ion-selective electrode measurement systems. The response of the electrode should not be slow and the theoretical slope of the electrode potential against logarithm of concentration plot at 25°C should be  $(58 \pm 1)/n$  mV where  $n$  is the number of electrons in the electrode reaction. Slow response times and deviations of slope from the theoretical value can indicate electrode faults and in water analysis particularly in *in situ* or continuous monitoring this can be due to fouling of the electrode by contaminants in the solution. The contaminants can sometimes be removed and the electrode will then function normally. The response time in flowing systems has to be carefully investigated because a slow response time may simply be associated with the passage of solution through the system flow cell rather than an electrode fault. Drift in the potential value obtained from the electrode can be due to temperature variation or in some cases inadequate stirring or flow. Failure to obtain suitable readings on

the pH meter often arises from there being a loss of contact in the system. This can be due to incompatible leads, bubbles in the system, and draining of solution from either external or internal reference electrodes. Electrical noise is often significant in ion-selective electrode measurements and care should be taken over the shielding of the electrodes. Particular problems arise in continuous flow systems often associated with noise from the pumping system.

The sequence of analytical measurements made in using the ion-selective electrode is carried out in the following stages: sampling, sample treatment, analysis, data acquisition, and data presentation. The sampling situation may involve discrete sampling, *in situ* sampling, or continuous monitoring.

## Sampling

The need for correct sampling procedures is particularly acute in the analysis of water samples. It is not possible to analyze the whole of a water body. The analysis may vary with position and time within the water body. In general, it is necessary to select positions so that the required information on the whole of the water body can be inferred from the sample. It is also necessary to ensure that the concentrations within the sample do not change from sampling to determination. The time variation in sampling can be overcome by the use of *in situ* measurement ('in line' or 'in stream' measurement) and ion-selective electrodes are particularly useful from this viewpoint; however, the use of this kind of measurement is not yet widespread. An alternative approach is to divert a stream of the water and carry out continuous analysis and this has been done in several cases. This type of measurement is known as online or on-stream measurement.

## Ion-Selective Electrodes for Use in Water Analysis

The ion-selective electrodes used in analysis are based on a system that comprises the ion-selective electrode membrane and a reference electrode. A variety of electrode types can be used for the analysis of species in water and these are described below, but the most important is undoubtedly the glass electrode. The glass electrode is used primarily for the determination of the pH of water samples and is widely used in water analysis.

### The Glass Electrode for the Determination of pH

The glass electrode is used for the measurement of the pH of natural waters. The electrode type can be

quite varied in terms of the size of the electrode probe, but the most common has a 1.2 cm thick stem that is ~12 cm long with a spherical bulb electrode at the end. The majority of electrodes have a silver/silver chloride internal reference electrode. The internal filling solution is a pH buffer solution and a chloride salt such as potassium chloride. The internal fill solution is chosen so that the electrode electromotive force (emf) is zero when the electrode is used with the appropriate external reference electrode, which is often a calomel electrode (either with a saturated or  $3.5 \text{ mol dm}^{-3}$  potassium chloride filling solution). Combined electrodes are now very common for pH measurement and these have an integral external reference electrode to which the solution to be measured has access through a ceramic frit liquid junction at the side of the lower part of the electrode. There are a wide variety of commercial pH meters available. The pH meter must be a specially designed meter that has an input impedance in excess of  $10^{12} \Omega$ .

The electrodes are normally stored in distilled or deionized water and should be rinsed with deionized water before use. The electrodes can be dried by draining the excess water off onto a tissue. The electrode must be standardized by immersion in buffer solutions whose pH are well separated. The procedure is to immerse the electrodes in the buffer solution for a period of 1 min with continuous stirring and observe the value which is then adjusted to the buffer value by the pH or calibration control. The electrode is then rinsed and dried and immersed in the second buffer solution and allowed to equilibrate for 1 min with stirring and the second buffer value is read. If this differs from that which is expected then the slope control of the pH meter should be altered. This whole procedure is then repeated until the values obtained in the buffer solutions at each end of the pH range agree with those of the known buffer solution.

**Measurements in low-conductivity waters** There has been a recent increase in interest in the measurement of pH in low ionic strength waters from upland areas because of the need to assess acidification of these waters. In low ionic strength waters, i.e., those that have a conductivity of less than  $100 \mu\text{S cm}^{-1}$ , problems in pH measurement can arise that are associated either with the low-conductivity solution or variation in the liquid junction potential. The variation in liquid junction potential is caused by blockage of the junction with precipitates and this is more of a problem for the silver/silver chloride reference electrode than the saturated calomel electrode. The problem of measurement in

low-conductivity solutions can be overcome if the electrodes used for measurement are performing correctly and this can be shown by a series of tests on them. At 25°C, the electrode slope factor should be within the range of  $58 \pm 1$  mV/pH unit. The residual liquid junction error that is estimated by measurement in a  $10^{-4}$  mol dm $^{-3}$  hydrochloric acid or sulfuric acid solution (a low-conductivity analytical quality control standard) and subtraction of the value 4.005 should be less than 0.05 pH. The pH shift on stirring obtained by comparison of the value obtained in the  $10^{-4}$  mol dm $^{-3}$  hydrochloric acid or sulfuric acid solution should be less than 0.02 pH and the noise in the pH measurement should be less than 0.02 pH.

The problem of the low conductivity of the water samples has also been addressed by modifications to the glass electrode and special low-resistance glasses have been developed to alleviate the problems associated with the low conductivity of the sample. These electrodes have impedance in the region of 5 M $\Omega$ .

Automated systems for low-conductivity waters are commercially available and have been produced specifically for use with the low-conductivity waters that are found in power stations.

**The glass electrode and sodium ion determination** The glass electrode can also be used for sodium ion determination and several commercial glass electrodes suitable for sodium ion determination are available. There is a very significant danger of sodium contamination of samples in a laboratory since there are many possible sources of sodium contamination. It is essential to avoid glassware in sodium ion determinations and plastic apparatus should be used. Equipment is commercially available for the online monitoring of sodium. Care is taken in such equipment to avoid the possibility of contamination of the sample and in one commercial instrument the water only comes into contact with Perspex, silicone rubber, stainless steel, and nonhalogenated plastics.

### The Fluoride Ion-Selective Electrode

Fluoride is naturally occurring in some waters and is added in small amounts to drinking waters. A level of 1 mg dm $^{-3}$  is recommended as being beneficial to the health of teeth and the limits in the United Kingdom for fluoride lie between 0.8 and 1.2 mg dm $^{-3}$ .

The fluoride ion-selective electrode is a particularly useful electrode in water analysis and is the basis of legislative procedures for the analysis of waters and effluents. The determination of fluoride ion in waters using the fluoride ion-selective electrode is not free from interferences. Consequently, although many potable waters can be determined directly some

cannot. The limit of detection of the ion-selective electrode method is 0.1 mg dm $^{-3}$ .

The fluoride ion-selective electrode responds directly to hydroxide ion but to few other common ions. The effect of the hydroxide ion is of concern if the fluoride ion concentration is not greater than 10 times that of the hydroxide ion. There are also problems, however, if the solution is too acidic as the formation of hydrogen fluoride reduces the concentration of fluoride. As a consequence of this, a total ionic strength adjustment buffer is used to maintain the pH between 5 and 6.

The fluoride ion-selective electrode is subject to interference by polyvalent cations, e.g., Ca $^{2+}$ , Fe $^{2+}$ , and Al $^{3+}$ , either acting on their own or in combination with other species and a complexant 1,2-diamino-cyclohexane-*N,N,N',N'*-tetraacetic acid is used to preferentially complex the interfering metal ions.

The fluoride ion-selective electrode requires equilibration time that is  $\sim 7$  min at concentrations of 0.1 mg dm $^{-3}$ .

**Electrode requirements** The calomel reference electrode should be of the sleeve tip rather than the fiber or ceramic plug type and care should be taken with the replacement of the reference electrode solution. The fluoride ion-selective electrode consists of a europium-doped lanthanum fluoride crystal. The emf response of the electrode to standard solutions should not be less than 55 mV over the range of concentrations of 0.2–200 mg dm $^{-3}$ . Values of the emf response lower than this can arise from poor matching of the sensor and reference electrodes, deterioration of the sensor electrode membrane, poor maintenance of the reference electrode, or poor maintenance of the sensor electrode. The analysis should be carried out in plastic vessels.

**Precautions in handling the fluoride ion-selective electrode** The lanthanum fluoride electrode is susceptible to mechanical damage and care should be taken to avoid situations where the electrode is subject to mechanical shock while in storage or use. If the electrode becomes coated with impurities it is possible to clean it by polishing with alumina on a suitable cloth. The electrode should not be subjected to solutions of pH less than 4 or fluoride concentrations greater than 20 g dm $^{-3}$ . The electrode will deteriorate depending on the amount of use it is subjected to within  $\sim 6$  months to 1 year.

### Ion-Selective Electrodes for the Determination of Ammonia

The electrodes that can be used for determining ammonia are the gas-sensing membrane electrode, the

ammonium-sensitive liquid membrane electrode, and the ammonium-sensitive glass electrode. The gas-sensing membrane electrode is the most sensitive and selective and this consists of a glass inner electrode that senses the change in pH of a film of ammonium salt solution trapped between the end of the glass electrode and a polymer membrane. The ammonium-sensitive liquid membrane electrode has been successfully used in pure waters such as boiler feed waters where it is more subject to alkali metal effects and has a higher limit of detection than the gas-sensing electrode. The ammonium-sensitive glass electrode is only suitable for use in high-purity waters as it is subject to serious interferences from alkali metal ions.

#### Liquid Ion-Exchange Electrodes for the Determination of Nitrate

These electrodes have nitrate-sensitive ion-exchange material incorporated into poly(vinyl chloride)-based membrane electrodes. Care is necessary to avoid contamination by the chloride from the saturated calomel reference electrode and a mercury/mercurous sulfate electrode is preferable as a reference electrode. Industrial monitors using nitrate ion-selective electrodes are commercially available.

#### Water Hardness Measurement

Water hardness is the total calcium and magnesium ion concentration in a water sample and is expressed as the concentration of calcium carbonate. Temporary hardness is that part of the total hardness that disappears on boiling. Whilst not being accepted as a standard method, the use of ion-selective electrodes allows a rapid measurement of water hardness and can be used to determine changes in hardness. The direct potentiometric method is not recommended for the ion-selective electrode but an indirect potentiometric method involving ethylenediaminetetraacetic acid titration is recommended. The ion-selective electrode that is used is a liquid ion-exchange electrode that responds to the divalent ions magnesium and calcium.

#### Carbon Dioxide Determination

Electrodes for the measurement of carbon dioxide are of the gas permeable membrane type. The membrane of the electrode is permeable to carbon dioxide which diffuses into a layer of sodium hydrogen carbonate solution that is trapped between a glass electrode and the membrane. The solution reacts with the carbon dioxide producing a pH change that is sensed by the glass electrode. The probe measures the free carbon dioxide in the sample. If the sample is acidified to pH 5 on the introduction of the probe, then the total carbon dioxide in the sample can be determined.

### Continuous Monitoring and Analysis in Flowing Solutions

The experimental arrangement required for the use of the ion-selective electrode in continuous monitoring of natural waters is shown in Figure 1. This type of measurement allows 'online' or 'on stream' measurement. The water stream to be analyzed is fed to a constant head tank fitted with an overflow. The water is fed from the tank into the system where it is pumped through the flow cell and buffer is added to allow measurement to take place. The standard solution (calibrant) is fed in at timed intervals by opening the valve. One of the most important parts of the continuous monitoring apparatus is the flow cell and flow cells have been developed with low sample requirements to minimize the need for refilling the buffer and calibrant reservoirs.

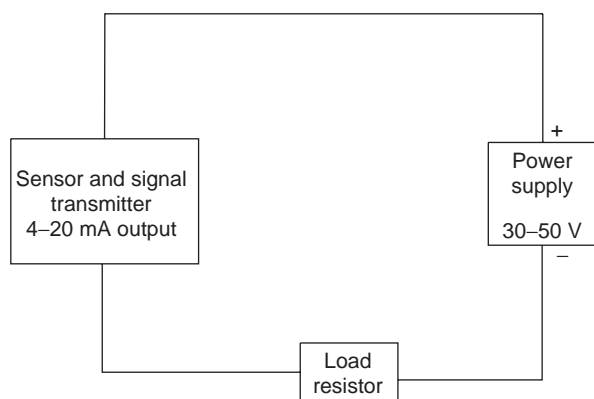

#### Instrumentation for Process Measurement

There are certain requirements for the instrumentation used in process measurement and standard measurement systems have been designed to allow these to be fulfilled. One of the most important aspects is ensuring that the signal can be read at a distance from the pH or ion-selective electrode without distortion due to electrical noise from the surrounding plant. The industrial standard method of doing this is to use a 4–20 mA loop (Figure 2).

The power supply supplies the power to the electronics associated with the sensor. The sensor returns a current that lies between 4 and 20 mA corresponding to its full output range. This current is converted to a voltage by the load resistor in the 4–20 mA loop which is typically a 500  $\Omega$  resistor giving a signal range from 2 to 10 V. The 4 mA

**Figure 1** Continuous monitoring using an ion-selective electrode.

**Figure 2** The 4–20 mA loop for signal transmission in process plant.

output that corresponds to the minimum output of the sensor allows a fault condition giving rise to 0 V to be distinguished from the minimum sensor output.

One of the primary advantages of the 4–20 mA analog communication is that the same two wires that are used to power the sensor also carry the signal output. The 4–20 mA system can transmit the signal over some kilometers. In addition, it is difficult to create unwanted current flows in the signal wire due to induced voltages as such voltages are small and are swamped by the loop driving voltage. With current signal-processing technology the sensor and associated electronics can be powered by a single shielded twisted wire pair that can also carry the output signal and in addition can also carry set-up calibration and sensor integrity information between the sensor and the control system. The electronics that convert the ion-selective or pH electrode signal to the 4–20 mA output are normally separate from the electrode and form part of the pH or ion-selective electrode meter.

### Noise Sources

In any process plant there will be several sources of electrical noise. The most common source is from 240 V, 50 Hz alternating current power circuits that can often be near to the electrodes and these result in sinusoidal interference signals at 50 Hz. Fluorescent lighting is also a common interference where the frequency of the interference is twice that of the mains supply voltage, i.e., 100 Hz. There may be additional noise sources in plant such as pumps or machinery, which require higher power levels than the normal main supply. It is important to have a clear understanding of the noise sources that can affect the measurement system and more details of these are given in the work by Bentley cited in the Further Reading section.

### Continuous pH Measurement

The pH meters used for continuous industrial measurement commonly have a standard 4–20 mA output. The amplifier unit will usually drive a separate display element remote from the measurement point. The pH electrode needs to be close to the amplifier since the electrode has very high impedance and hence requires short leads and careful screening. The amplifier will need to be protected against its environment and also the environment will need to be protected from the electrical hazard posed by the amplifier. Suitable intrinsically safe pH amplifier systems can be obtained commercially. Only the electrodes and the amplifier need to be located in the hazardous area where the measurement is taking place whereas the other equipment and display element can be located in a safe area.

The glass electrode for pH measurement is sufficiently stable to allow calibration at reasonably large intervals of time, most probably of the order of once a week and hence it is generally the case that pH electrodes are calibrated manually.

### In Situ pH Measurement

The pH electrode may be used to make measurements of the hydrogen ion activity by directly immersing the electrodes in the water flow. In this case, it is not possible to buffer the solution and since the pH measurement is normally made in this way there is no problem for pH measurement. Other ion-selective electrodes tend not to be used in this way as activity measurements are not normally used for other ions. Special cells are required for pH measurements, which are carried out *in situ*. These are of two types: cells for use in pipework where the cell is part of the pipe that carries the water, and dip cells that are used to dip the electrodes into ponds, lakes, reservoirs, and other water supplies.

### Continuous Ion-Selective Electrode Measurement

For ion-selective electrodes, in general, more frequent calibration is needed than for the glass electrode for the measurement of pH. As a consequence, automatic calibration systems have been developed. These systems allow automatic chemical standardization at set intervals, e.g., 3, 6, 12 h or 1, 2, 4, 8 days. The systems also allow manual or remote initiation of the standardization sequence at any time. The standardization systems are generally operated by solenoid valves, which stop the sample flow and allow the calibration solution to be fed into the cell. When the sensor has stabilized in the new solution the amplifier output is compared with a preset calibration value and any difference between the

calibration value and the preset value is backed off the amplifier output to adjust it to the correct value. The solenoid valve is then returned to its original position so that the sample can be monitored.

## Other Electrode Types

### Ion-Selective Field-Effect Transistors

Ion-selective field-effect transistors (ISFETs) are potentiometric sensors in which there is direct contact between the electroactive coating and the electrolyte. The ISFET works on the principle that the chemically sensitive layer responds to the analyte, and its potential with respect to the reference electrode is altered. The chemically sensitive layer is mounted on an insulator above the space between two n-type contacts to a silicon chip. The reference electrode is also connected to the silicon chip so that when the potential of the coating changes the potential in the region of the two n-type contacts also changes. The current flowing between the two n-type contacts is very dependent on the potential in this region and as a consequence of this the current is also sensitive to the presence of the analyte. Significant amplification of the signal due to the analyte is achieved in the ISFET.

The ISFETs are electrodes that are currently commercially available and include electrodes for the measurement of pH. The small size of the electrode and its lack of fragility are advantages that are important in other areas than water analysis, but the local amplification of the signal is likely to prove useful in water monitoring situations.

### Enzyme Electrodes

The use of enzyme-based electrodes has been particularly important in electrode development in the biosensing field and enzymes greatly enhance the specificity of the electrodes. The enzyme electrodes can be either potentiometric or voltammetric. Since electrodes based on enzymes are often stable over relatively short periods, electrodes with replaceable enzyme tips may prove useful in water monitoring.

### Introduction

Isotope dilution analysis (IDA) involves the modification of the natural isotopic composition of a target

analyte, contained within a sample, by the addition of an accurately known amount of an isotopically enriched analog (or spike) of the analyte. The concentration of the target analyte can then be calculated by measuring the resultant modified isotope amount ratio. The process is shown schematically in **Figure 1**. The modified isotope amount ratio can be measured using either mass spectrometry or radiochemical methods. It is isotope dilution mass

**Figure 1** Schematic representation of isotope dilution analysis showing the relative amounts of two isotopes, A and B, in the sample, the spike, and an equimolar mixture of the two. The figures in parentheses are the percent abundances of the isotopes before and after mixing. The example shown reflects the isotopic abundance of Hg and the figures do not add to 100% because several other isotopes contribute to the total (Table 3).

spectrometry (ID-MS) that will be described in detail here, though the general principles are much the same.

IDA is regarded as a definitive analytical technique because:

- it is directly traceable to SI units;
- the precision and accuracy obtainable are unsurpassed by alternative analytical methods; and
- it can account for analyte losses or incomplete extraction.

In ID-MS a spike solution, containing the isotopically enriched analog of the analyte, is added to the sample containing the natural abundance analyte. In order to measure the isotope ratio two isotopes (for inorganic ID-MS) or isotopomers (for organic ID-MS) are chosen, the sample (A) and the spike (B). The sample isotope, or isotopomer, is usually most abundant in the sample and the spike isotope, or isotopomer, is most abundant in the spike solution.

It should be noted here that there are some fundamental differences between organic and inorganic ID-MS. In organic ID-MS, the isotopically enriched analog is an organic molecule that has been labeled with (usually) either  $^{13}\text{C}$ ,  $^2\text{H}$ , or  $^{15}\text{N}$  on a nonlabile site. In order to prevent interference from low abundance isotopomers multiple labeling is usually performed so that the mass of the labeled spike differs from the analyte by at least 3 mass units. The spike isotopes have extremely low abundances in nature (Table 1), so the labeled spike isotopomer is of extremely low abundance in the sample. Conversely,

**Table 1** Natural atom fraction abundances of H, C, and N

Isotope	Natural abundance (%)
$^1\text{H}$	99.9
$^2\text{H}$	0.01
$^{12}\text{C}$	98.9
$^{13}\text{C}$	1.1
$^{14}\text{N}$	99.6
$^{15}\text{N}$	0.36

the sample isotopomer will be of extremely low abundance in the spike (Table 2).

In inorganic IDMS, the isotopically enriched analog is not an array of individual labeled molecules, but rather a mixture of individual isotopes that contribute directly to the enrichment of the array, but in different proportion to the sample (Table 3 and Figure 1). Ideally, the sample isotope should be of low abundance in the spike, and the spike isotope should be of low abundance in the sample, but this is very often not the case (Table 3). The isotope ratio is measured by ratioing the signal strengths of the spike and sample isotopes at their corresponding masses.

## Theory

### Inorganic ID-MS

The sample containing the analyte is spiked with the isotopically enriched analog. The sample isotope (A) and the spike isotope (B) are ratioed to give an isotope amount ratio ( $R_B$ ) in the sample/spike blend. This is a ratio of the number of moles of isotope A to the number of moles of isotope B, originating from both the sample and spike, and is given by eqn [1]:

$$R_B = \frac{A_y \cdot n_y + A_x \cdot n_x}{B_y \cdot n_y + B_x \cdot n_x} \quad [1]$$

where  $A_y$  is the isotope amount fraction of isotope A in the spike,  $A_x$  the isotope amount fraction of isotope A in the sample,  $B_y$  the isotope amount fraction of isotope B in the spike,  $B_x$  the isotope amount fraction of isotope B in the sample,  $n_y$  the number of moles of analyte in the spike solution, and  $n_x$  the number of moles of analyte in the sample.

Note that the subscript  $x$  is used to denote material of natural isotopic abundance and the subscript  $y$  is used to denote isotopically modified material.

Equation [1] can be solved for  $n_x$ , the amount in moles of analyte originally present in the unspiked sample (eqn [2]):

$$n_x = n_y \cdot \frac{A_y - R_B \cdot B_y}{R_B \cdot B_x - A_x} \quad [2]$$

**Table 2** Reference and spike masses of unlabeled and phenyl-<sup>13</sup>C6 (atom 90% enriched) labeled sulfamethazine

Isotopomer mass (Da)	Structure	Relative abundance	
		Sample	Spike
278 (sample)		1.0	<0.001
284 (spike)		<0.001	1.0

The relative abundances of the sample and spike isotopomers are given at the masses shown, not the abundances of all possible isotopomer masses.

**Table 3** Overall abundances in an array of <sup>199</sup>Hg-enriched Hg atoms in the sample and spike

Isotope	Overall Isotopic abundance in the array (%)	
	Sample	Spike
<sup>196</sup> Hg	0.15	0.15
<sup>198</sup> Hg	9.97	2.93
<sup>199</sup> Hg (spike)	16.87	65.98
<sup>200</sup> Hg (reference)	23.1	18.15
<sup>201</sup> Hg	13.18	3.96
<sup>202</sup> Hg	29.86	7.43
<sup>204</sup> Hg	6.87	1.44

It is more usual to quote the analytical result as a mass fraction, thus eqn [3] is used for the IDA calculation:

$$c_x = \frac{c_y w_y M_x}{w_x M_y} \frac{A_y - R_B \cdot B_y}{R_B \cdot B_x - A_x} \quad [3]$$

where, in addition,  $c_x$  is the mass fraction of analyte in the sample,  $c_y$  the mass fraction of analyte in the spike,  $w_y$  the mass of spike,  $w_x$  the mass of sample,  $M_x$  the molar mass of analyte in the sample, and  $M_y$  the molar mass of analyte in the spike.

Alternatively, the atom fraction ( $f$ ) can be calculated according to eqn [4], where one isotope is chosen as a reference isotope ( $r$ ) and the other isotopes are referenced to it (including the reference isotope). Hence, for an element having  $i$  isotopes the atom fraction of isotope  $q$  ( $f_q$ ) is given by

$$f_q = \frac{n_q/r}{\sum_i n_i/r} \quad [4]$$

where  $n_q$  is the isotope amount fraction of isotope  $q$ ,  $n_i$  the isotope amount fraction of isotope  $i$ , and  $r$  the isotope amount fraction of the reference isotope.

By using the terminology in eqn [2], where the subscript  $y$  denotes the enriched spike material and the subscript  $x$  denotes the natural isotopic abundance analyte in the sample, the isotope amount fractions can be expressed in the form of eqn [4]. If the spike isotope ( $B$ ) is used as the reference isotope then the isotope amount fraction of isotope  $A$  to isotope  $B$  in the spike ( $A_{\text{spike}}$ ) can be expressed as (eqn [5])

$$A_{\text{spike}} = \frac{A_y/B_y}{\sum_i n_y/B_y} \quad [5]$$

which can be simplified to (eqn [6])

$$A_{\text{spike}} = \frac{R_y}{\sum_i R_{iy}} \quad [6]$$

where  $R_y$  is the isotope amount ratio of isotope  $A$  to  $B$  in the spike,  $\sum_i R_{iy}$  the sum of the atom fraction ratios of all isotopes to the reference isotope.

Similarly, the isotope amount fractions of the spike and sample isotopes in the spike and sample ( $B_{\text{spike}}$ ,  $A_{\text{sample}}$ ,  $B_{\text{sample}}$ ) can be expressed as

$$B_{\text{spike}} = \frac{B_y/B_y}{\sum_i n_y/B_y} = \frac{1}{\sum_i R_{iy}} \quad [7]$$

$$A_{\text{sample}} = \frac{A_x/B_x}{\sum_i n_x/B_x} = \frac{R_x}{\sum_i R_{ix}} \quad [8]$$

$$B_{\text{sample}} = \frac{B_x/B_x}{\sum_i n_x/B_x} = \frac{1}{\sum_i R_{ix}} \quad [9]$$

where  $R_x$  is the isotope amount ratio of  $A$  to  $B$  in the natural sample and  $\sum_i R_{ix}$  the sum of the atom fraction ratios of all isotopes to the reference isotope.

Thus, the isotope amount ratio,  $R_B$ , of the sample to spike isotopes in the sample/spike blend can also be written as

$$R_B = \frac{(R_y / \sum_i R_{iy})n_y + (R_x / \sum_i R_{ix})n_x}{(1 / \sum_i R_{iy})n_y + (1 / \sum_i R_{ix})n_x} \quad [10]$$

which can be solved for  $n_x$ , the number of moles of analyte present in the unspiked sample giving eqn [11]:

$$n_x = n_y \frac{R_y - R_B \sum_i R_{ix}}{R_B - R_x \sum_i R_{iy}} \quad [11]$$

In this form of the ID-MS equation, the amount of substance can be directly replaced by an amount content (e.g.,  $\text{mol kg}^{-1}$ ) or mass fraction (e.g., ng per g), or any other appropriate unit provided the use of units remains constant throughout. Thus, eqn [11] can be expressed in terms of a mass fraction:

$$c_x = c_y \frac{m_y R_y - R_B \sum_i R_{ix}}{m_x R_B - R_x \sum_i R_{iy}} \quad [12]$$

where, in addition,  $c_x$  is the mass fraction of the analyte in the unspiked sample,  $m_x$  the mass of the sample,  $c_y$  the mass fraction of the isotopically modified spike, and  $m_y$  the mass of the isotopically modified spike added to the sample.

The advantage of using eqn [12] rather than eqn [3] is that the isotope amount fractions in the sample and the spike are not correlated, which simplifies the calculation of the measurement uncertainty of the analytical result.

### Organic ID-MS

The theory is identical for organic ID-MS but can be simplified somewhat. Organic compounds are usually labeled with  $^{13}\text{C}$ ,  $^2\text{H}$ , or  $^{15}\text{N}$ , each of which have only two isotopes (Table 1), so eqn [12] can be further simplified to

$$c_x = c_y \frac{m_y R_y - R_B R_x + 1}{m_x R_B - R_x R_y + 1} \quad [13]$$

A further simplification can be made if the spike isotope is of extremely low natural abundance and there is very little of the spike isotopomer in the sample. In this case,  $R_x$  tends toward infinity, so eqn [13] can be simplified to

$$c_x = c_y \frac{m_y R_y - R_B}{m_x R_y + 1} \quad [14]$$

If the isotopically enriched analog is of high purity and there is very little of the sample isotopomer present in the spike, then  $R_y$  tends to zero and a

further simplification can be made:

$$c_x = c_y \frac{m_y}{m_x} R_B \quad [15]$$

### Practice

The successful practice of IDA by mass spectrometry depends on a number of factors:

- more than one stable isotope (or isotopomer) in the spike and sample must exist;
- the isotopically differentiated peaks in the mass spectrum must be free from interference;
- an isotopically enriched analog, or spike, of the analyte must be available;
- complete equilibration between the spike and sample must be achieved;
- the mass fractions and isotopic abundances of sample and spike isotopes must be well characterized; and
- the spike and sample must be chemically stable.

### Isotopic Standards

The isotopic abundance of the naturally occurring isotopes in the sample and the isotopically enriched analog in the spike must be well characterized. This can be a particular problem in inorganic ID-MS if isotopes of the analyte in the sample vary in nature, or are man-made (e.g., as a result of nuclear reactions). If this is the case the isotopic abundances must first be determined before IDA can proceed. Isotopically enriched spike compounds can normally be purchased with a certificate stating concentration and isotopic abundance; however, it is good practice to at least verify the concentration. If the purity of the isotopically enriched analog has been characterized with sufficient accuracy and minimal uncertainty, the concentration can be calculated simply from knowledge of the masses of the compound and solvent employed. If the purity of the spike material is not certain, then reverse IDA is employed. In this case, the enriched spike material is treated as the sample and the isotopic abundance is modified by the addition of a certified standard of natural isotopic abundance that acts as the spike material.

### Spiking Procedure

In order to reduce systematic errors, such as ion counting errors due to detector dead time, it is better to fix the isotope amount ratio as close to unity as possible. In order to do this it is necessary to know the approximate concentration of the analyte in the sample prior to spiking. An exact 1:1 isotope amount ratio can be achieved by using an iterative matching

procedure; however, this can add considerable time to the method and is not always necessary. An approximate matching procedure confers many of the benefits of the exact matching procedure but is less time consuming. To avoid matrix effects and dilution of the sample, the spiking procedure follows the convention that the spike should be added in a small volume of a relatively high concentration.

For inorganic ID-MS, error propagation plots can be used to calculate the optimum analyte-spike isotope amount ratio for the minimization of errors during the measurement of the isotope amount ratio. This ratio can be calculated for a particular isotope pair using eqn [16], examples of which are shown in Figure 2. In practice, the isotope amount ratio should lie between 1:4 and 4:1 to give a reasonable signal for each isotope, and it is probably simplest to use an isotope amount ratio as close to unity as possible:

$$\sqrt{(B_y/A_y) \times (B_x/A_x)} \quad [16]$$

where  $A_y$  is the abundance of the sample isotope in the spike,  $B_y$  the abundance of spike isotope in the spike,  $A_x$  the abundance of sample isotope in the sample, and  $B_x$  the abundance of spike isotope in the sample.

### Extraction and Equilibration

A major advantage of IDA is that complete extraction of the analyte from the sample matrix is not

necessary to achieve accurate results; however, complete equilibration of the spike and sample isotopes is vital.

For the determination of organic compounds by IDA it is necessary to extract the analyte from the sample without causing chemical breakdown of the analyte. Complete extraction of the analyte from the sample is not necessary for successful IDA but it is important to ensure complete equilibration of the spike and sample, such that partitioning between solid, liquid, and gaseous phases is the same for both the spike and sample isotopomers. For example, if solvent extraction of a compound from a soil sample is undertaken, the spike and analyte should partition to the same extent between the solvent and soil particles.

In comparison, for elemental analysis, the integrity of the analyte is not an issue, so much harsher sample pretreatment can be performed using inorganic acids. This breaks down the sample and extracts the analyte completely into the liquid phase. However, it is still necessary to ensure that the spike and sample isotopes are in the same chemical form, so repeated oxidation/reduction cycles may be necessary. This is particularly true if thermal ionization mass spectrometry (TIMS) is used, because different inorganic oxidation states can have quite different thermal properties.

### Measurement of Isotope Amount Ratios

Once the sample has been spiked, equilibrated, and prepared in a way suitable for introduction into the instrument, the sample-spike isotope amount ratio ( $A:B$ ) must be measured. The observed isotope amount ratio must be corrected for the effects of spectroscopic interferences, mass fractionation in the sample introduction system and/or ion source, and mass bias in the mass spectrometer and associated ion optics.

**Spectroscopic interferences** Nonspectroscopic instrumental interferences are accounted for because they have the same effect on both the spike and sample signals, so are cancelled in the measured isotope amount ratio. However, spectroscopic interferences often apply to either the spike or sample isotopes alone and so are not accounted for. In inorganic ID-MS, simple isobaric interferences such as  $^{204}\text{Hg}$  on  $^{204}\text{Pb}$  can be corrected for by measuring the signal at  $^{202}\text{Hg}$  and using an elemental equation to obtain the true signal for Pb at  $m/z$  204:

$$^{204}\text{Pb}_{\text{true}} = ^{204}\text{Pb}_{\text{obs}} - (^{202}\text{Hg}_{\text{obs}} \times (a_{204\text{Hg}}/a_{202\text{Hg}})) \quad [17]$$

where  $^{204}\text{Pb}_{\text{true}}$  is the true signal for  $^{204}\text{Pb}$  at  $m/z$  204,  $^{204}\text{Pb}_{\text{obs}}$  the observed signal for  $^{204}\text{Pb}$  at  $m/z$  204,

**Figure 2** Error factors calculated for different isotope amount ratios of Zn and Se. (Adapted from Clough RC, Truscott J, Belt ST, *et al.* (2003) Isotope dilution ICP-MS for speciation studies. *Applied Spectroscopy Reviews* 38: 101–132.)

$^{202}\text{Hg}_{\text{obs}}$  the observed signal for  $^{202}\text{Hg}$  at  $m/z$  202,  $a_{204\text{Hg}}$  the atom fraction of the  $^{204}\text{Hg}$  isotope, and  $a_{202\text{Hg}}$  the atom fraction of the  $^{202}\text{Hg}$  isotope. If the interference is caused by a polyatomic ion (e.g.,  $^{40}\text{Ar}^{16}\text{O}^+$  on  $^{56}\text{Fe}$ ) the interference can sometimes be removed instrumentally or resolved if the mass spectrometer has sufficient resolving power.

Likewise, in organic ID-MS, multiple labeling of the isotopically enriched spike is usually performed so that its mass differs from the analyte by at least 3 mass units. This ensures that interference from the  $^{13}\text{C}$  sample isotopomer at  $M + 1$  does not occur.

**Mass fractionation** It occurs when the spike and sample isotopes, or compounds that contain them, undergo differential separation during the sample introduction or ionization process. For example, if the analyte is introduced as a gas, molecules containing the lighter of the sample or spike isotopes will diffuse slightly quicker than molecules containing the heavier isotope, hence mass fractionation will occur. This is a particular problem when gas chromatography is used as the sample introduction method and, in extreme cases, two distinct chromatographic peaks will result. For the same reason, mass fractionation can occur during the combustion stage in isotope ratio mass spectrometry, or in ionization sources that rely on thermal ionization processes such as TIMS.

If fractionation occurs in a chromatographic step then each complete peak must be integrated and the integral used to calculate the isotope amount ratio.

**Instrumental mass bias** It occurs because mass spectrometers and their associated ion optics do not transmit ions of different mass equally. In other words, if a sample composed of two isotopes with an exactly 1:1 molar ratio is analyzed, a 1:1 isotope amount ratio will not necessarily be observed. This so-called mass bias depends on mass and the type of mass spectrometer used, but generally tends to be greatest at low mass, and decreases with increasing mass. Even very small mass-biases can have deleterious effects on the accuracy of ID-MS, so a correction must often be made, usually in one of two ways as follows.

**Bracketing** If an isotopic standard of known composition for the isotope pair under study is available, then a correction can be applied as shown in eqn [18]:

$$C = \frac{R_{\text{true}}}{R_{\text{obs}}} \quad [18]$$

where  $C$  is the mass bias correction factor,  $R_{\text{true}}$  the true or certified isotope amount ratio for the isotope pair, and  $R_{\text{obs}}$  the observed or measured isotope amount ratio for the isotope pair. In practice, the isotopic standard is analyzed before and after the sample (i.e., the sample is bracketed) and the mean correction factor calculated for the bracketing pair is applied to the sample.

**Interpolation** In inorganic ID-MS, it is also possible to use an alternative element, with an isotope pair of similar mass to the isotope under study, and which has a certified isotope amount ratio. The mass bias correction can be performed by interpolating (with increasing accuracy), using either linear, power, or exponential equations:

$$\text{Linear} \quad \frac{R_{\text{obs}}}{R_{\text{true}}} = 1 + B\Delta m \quad [19]$$

$$\text{Power} \quad \frac{R_{\text{obs}}}{R_{\text{true}}} = (1 + B)^{\Delta m} \quad [20]$$

$$\text{Exponential} \quad \frac{R_{\text{obs}}}{R_{\text{true}}} = \exp(B\Delta m) \quad [21]$$

where  $B$  is the mass bias and  $\Delta m$  the mass difference between the isotopes used to calculate the ratio,  $R$ .

The Russell correction is a particular case of the generalized power law:

$$\text{Russell} \quad \frac{R_{\text{obs}}}{R_{\text{true}}} = \left(\frac{m_2}{m_1}\right)^f \quad [22]$$

where  $m_1$  and  $m_2$  are the masses of the isotopes used to calculate the ratio,  $R$ ; and  $f$  is the mass bias correction factor. For example, the  $^{205}\text{Tl}/^{203}\text{Tl}$  ratio can be used to correct the mass bias of  $^{200}\text{Hg}/^{199}\text{Hg}$  using the Russell correction as shown in eqn [23]:

$$\left(^{200}\text{Hg}/^{199}\text{Hg}\right)_{\text{true}} = \frac{\left(^{200}\text{Hg}/^{199}\text{Hg}\right)_{\text{obs}}}{\left[\frac{\left(^{205}\text{Tl}/^{203}\text{Tl}\right)_{\text{obs}}}{\left(^{205}\text{Tl}/^{203}\text{Tl}\right)_{\text{true}}}\right]^{\left[\frac{\ln(M^{200}\text{Hg}/M^{199}\text{Hg})}{\ln(M^{205}\text{Tl}/M^{203}\text{Tl})}\right]}} \quad [23]$$

where  $M$  is molar mass of the isotope.

The advantage of this approach is that the mass bias correction can be performed by spiking the sample with a mass bias correction standard (e.g., Tl) and measuring this isotope amount ratio at the same time as the sample.

**Detector dead time** Also important is the effect of detector dead time when using certain types of detector. For example, when ions are detected using an

electron multiplier in pulse counting mode the resultant electronic pulses are  $\sim 10$  ns long. During and after each pulse there is a period of time during which the detector is effectively 'dead' (i.e., it cannot detect any ions). The dead time is made up of the time for each pulse and recovery time for the detector and associated electronics. Typical dead times vary between 20 and 100 ns. If dead time is not taken into account there will be an apparent reduction in the number of pulses at high count rates, which would cause an inaccuracy in the measurement of isotope ratios when abundances differ markedly. However, a correction can be applied as shown in eqn [24]:

$$C_{\text{true}} = \frac{C_{\text{obs}}t}{t - C_{\text{obs}}D} \quad [24]$$

where  $C_{\text{true}}$  is the true number of counts,  $C_{\text{obs}}$  the observed number of counts,  $t$  the time spent monitoring each mass, and  $D$  the dead time.

The corresponding equation for count rate is

$$R_{\text{true}} = \frac{R_{\text{obs}}}{1 - R_{\text{obs}}D} \quad [25]$$

where  $R_{\text{true}}$  is the true count rate and  $R_{\text{obs}}$  the observed count rate.

If no dead time correction is applied then a linear calibration would not be possible, since the higher count rates between  $10^4$  and  $10^6$  Hz would be underestimated. This provides a way of determining the dead-time empirically, i.e., by re-integrating the isotopic signals with different dead times until a linear calibration is obtained for a series of accurately known standards.

A better method, which accounts for any instrumental drift, is to measure the isotope amount ratio of two isotopes with different abundances, and use the following expression:

$$(R_m - CR_M) = D[R_m R_M(1 - C)] \quad [26]$$

where  $R_m$  is the count rate of the minor isotope,  $R_M$  the count rate of the major isotope, and  $C = R_m/R_M$ .

The isotope amount ratio  $C$  must be calculated in absence of dead-time effects (i.e., at low count rates, but not so low as to give bad counting statistics) by repeated measurements of the blank subtracted isotope amount ratio. This is the instrumental isotope amount ratio, and no correction is made for mass bias. The count rates are then measured for a series of concentrations and the data, which has not been corrected for dead time, can be used to plot  $(R_m - CR_M)$  against  $[R_m R_M(1 - C)]$ , the slope of the line being equivalent to the dead time,  $D$ , in seconds. The data that are plotted must fall within the

range of count rates at which dead-time effects become significant (i.e., between  $\sim 10^3$  and  $\sim 10^6$  Hz); otherwise, a curve rather than a straight line will result. In practice, the effect of dead time will not be significant as long as the count rate is below  $10^5$  counts per second. More important is the effect of low count rate on precision, which means that the longest possible time should be allowed for ion counting when the count rate is below  $\sim 500$  counts per second, though this will depend on the amount of sample that is available.

**Blank correction** In order to achieve the best accuracy and precision, blank determinations should be made using the same procedure as for the sample; however, complications can arise.

If the blank signal is small, then it may not be possible to spike the blank to achieve the optimal ratio and still observe a measurable signal for both isotopes. In this case, the spike-sample ratio should be  $\sim 10:1$  to achieve best precision.

If the isotope abundances of the analyte isotopes vary in nature then the situation may arise where the isotopic abundances in the blank and sample differ (e.g., Pb contamination in reagents used for sample preparation). If the blank is large relative to the sample then it will make a significant contribution to the overall isotopic abundance of the sample when presented for analysis, which will be intermediate between the original sample and the blank. In this case, the isotopic abundances in the blank and the prepared sample (i.e., including the blank contribution) must be first determined, before the concentration of each can then be determined by IDA for subsequent blank subtraction. Alternatively, the blank signals for the spike and reference isotopes can be subtracted from the sample signals before the isotope amount ratio is calculated, though this will possibly cause a degradation in precision and accuracy.

## Applications of IDMS

### Elemental IDMS

Isotope dilution as a quantitative technique for elemental analysis was first applied by Reynolds, in 1950, to determine the amounts of decay products after neutron irradiation of  $\text{Cu}^{64}$ ,  $\text{Br}^{80}$ ,  $\text{Br}^{82}$ , and  $\text{I}^{128}$ . TIMS was the mainstay of this type of analysis for many years until the advent of inductively coupled plasma mass spectrometry (ICP-MS), which allows more rapid determination of a wider range of elements. The technique of IDA is traceable to the mole and so is the method of choice whenever a high

**Figure 3**  $^{200}\text{Hg}$ : $^{199}\text{Hg}$  and  $^{205}\text{Tl}$ : $^{203}\text{Tl}$  isotope amount ratios and  $^{200}\text{Hg}$  signal of 900 ng per g methyl mercury monitored using multicollector, magnetic sector ICP-MS. (Adapted from Clough *et al.* (2003) *Journal of Analytical Atomic Spectrometry* 18: 1039–1046.)

degree of accuracy, precision, and traceability is required, such as for the preparation of certified reference materials. It is also useful when analyte losses during sample preparation are likely to occur. The latest generation of ICP-MS instruments, equipped with double focusing magnetic sector analyzers and multiple, simultaneous ion detectors are capable of isotope amount ratio precision of 0.01% or better.

A recent development is species-specific IDA, whereby organometallic compounds or elemental species can be chromatographically separated, introduced into the ICP-MS instrument, and the isotope amount ratio of the elemental moiety can be determined for the purposes of IDA. An example of this is the speciation of methylmercury in environmental samples, where the sample is spiked with an analog of methylmercury enriched in  $^{199}\text{Hg}$ . The resulting multiple ion chromatogram obtained after online chromatographic separation is shown in **Figure 3**. The mass spectrum taken at the chromatographic peak is shown in **Figure 4**, with isotopic abundances of the Hg isotopes reflecting the mixing of the sample and spike (i.e., intermediate between the two).

### Organic IDMS

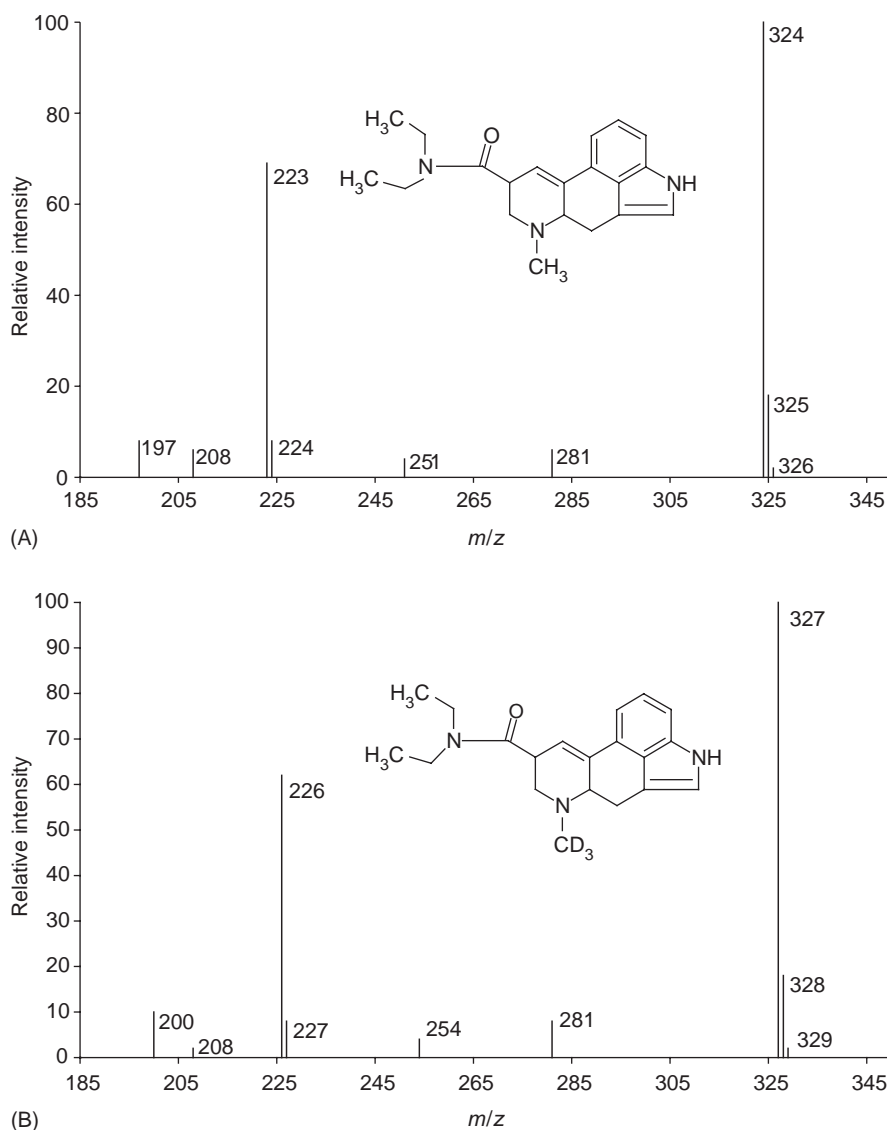

During the 1970s, isotope dilution was introduced for the quantitation of organic analytes by gas chromatography–mass spectrometry (GC–MS), with spike compounds labeled with  $^{13}\text{C}$ ,  $^2\text{H}$ , or  $^{15}\text{N}$ . Since then it has been used for the determination of compounds ranging from ethanol in water to cholesterol in human serum. ID-MS is ideally suited to this type of measurement because the complex sample matrix

**Figure 4** Mass spectrum of Hg taken at the chromatographic peak maximum shown in **Figure 3**.

presents difficulties when external calibration is applied, due to factors such as different analyte ionization efficiencies, unless the standards are closely matrix matched to the samples. For example, electrospray ionization mass spectrometry (ESI-MS), which is one of the most widely used methods for the determination of nonvolatile compounds, has greatly varying ionization efficiencies depending on the polarity and charge in solution of the analyte compound.

An example of using ESI-MS for IDA of lysergide is shown in **Figure 5**. In this case, the isotopically enriched analog has been triply deuterated so that the protonated molecular ion ( $M + H$ )<sup>+</sup>, which normally occurs at  $m/z$  324, is shifted to  $m/z$  327. Because the natural abundance of deuterium is so low (0.01%) the degree of enrichment of the deuterated spike isotopomer is extremely high, and so two distinct peaks appear in the mass spectrum, separated by 3 mass units.

**Figure 5** Structure and fragmentation induced ESI mass spectrum of lysergide, showing: (A) the natural abundance and (B) the deuterated analog. ## Introduction

Atomic nuclei (nuclides) consist of positively charged protons and uncharged neutrons; particles collectively known as nucleons, which interact through a short-range attractive force that holds the nucleus together. As the number of protons in the nucleus (the atomic number  $Z$ ) increases more neutrons are required to prevent the nucleus from breaking apart under the strain of proton–proton repulsion. Nuclides are most commonly referred to by the elemental symbol preceded by the mass number ( $A$ ), e.g.,  $^{12}\text{C}$ ,  $^{238}\text{U}$ . Isotopes are atomic species of the same element that differ in atomic mass; that is, nuclei with a given number of protons but differing numbers of neutrons. The term ‘isotope’ was first used by Soddy in 1913, the same year in which the existence of naturally occurring isotopes was first reported by J.J. Thompson, who discovered two stable isotopes of neon (mass 20 and 22) using one of the earliest mass spectrometers. Today, a range of isotopes has been discovered or made for every known element, the vast majority being made by nuclear reactions using man-made sources of nucleons.

The principle technique used for the measurement of isotope ratios is mass spectrometry (MS) using various combinations of ion source and mass analyzer for the analysis of many organic and inorganic materials. Less frequently employed are spectroscopic techniques such as optical absorption and emission, and nuclear magnetic resonance (NMR).

## Isotope Ratios

The precise and accurate determination of isotope ratios is applied to many different fields, such as: measurements of stable isotopes in nature, especially for the investigation of isotope variation in geological and cosmic samples or age dating; determining isotope ratios of radiogenic elements in the nuclear industry; quality assurance of fuel material for reprocessing plants; nuclear material accounting and radioactive waste control; and tracer experiments using highly enriched stable isotopes or long-lived radionuclides in biological or medical studies.

The elements that form biological molecules (hydrogen, carbon, nitrogen, oxygen, and sulfur) have

two or more stable isotopes, the lighter isotope in each case being far more abundant. Natural and artificial chemical reactions fractionate isotopes, thus leading to the occurrence of organic and inorganic materials with different isotopic compositions. Studies over 50 years have shown that isotopic fractionation due to physiological processes, specifically  $\text{CO}_2$  transport within plants and photosynthesis, leads to variations in  $^{13}\text{C}/^{12}\text{C}$  isotope ratios in natural compounds.

These variations result from a kinetic isotope effect (KIE), which is defined as the ratio of reaction rate constants for reactant molecules containing the light and heavy isotope:

$$\text{KIE} = k_{\text{light}}/k_{\text{heavy}}$$

KIEs depend upon differences in vibrational energy levels and are proportional to the square root of the inverse of the atomic mass. Hence, for heavy atoms the typical KIE will be very small ( $^{35}\text{Cl}/^{37}\text{Cl} \sim 1.01$ ) but increases rapidly as the atomic mass decreases ( $^{13}\text{C}/^{12}\text{C} \sim 1.04$  and  $^2\text{H}/^1\text{H} \sim 8$ ).

Isotopic composition can be expressed as either absolute or relative measurement, depending on the particular application. When isotopically labeled materials are used as tracers absolute values are determined. The isotopic (or radiochemical) purity is the percentage of label present in the specified chemical form that may include the position of the label or the enantiomorphic form of the compound. In contrast, radionuclidic purity is the percentage of the total radioactivity present as the specified radionuclide and implies nothing about the chemical form of the radionuclides present.

Relative measurements are most commonly used to express small variations in the natural abundance of ‘light’ stable isotopes and find applications in areas such as the geosciences and ecological research. No consensus exists on the appropriate units in which isotope ratios are reported, especially in the biomedical field. Most isotope ratio mass spectrometers (IRMS) report isotopic abundance in terms of delta notation (‘parts per thousand’ or ‘per mil’), which is a convention determined by geochemistry, because most of the original IRMS instruments were developed in isotope geochemistry laboratories. Delta units are not SI units. The SI base unit for quantity is the mole, from which atom fraction and mole fraction are derived. The units of stable isotope abundance, at.% and mol.%, are the atom and mole

fractions expressed as percentages. At.% excess and mol.% excess are the SI units of enrichment and are recommended for use in tracer studies.

## Absolute Abundance

Atom per cent (at.%) is an absolute measure of the number of atoms of a particular isotope present in 100 atoms of that element:

$$\begin{aligned}\text{For example, at.\% } ^{15}\text{N for air} \\ &= \left( \frac{^{15}\text{N}/^{14}\text{N}}{^{15}\text{N}/^{14}\text{N} + 1} \right) \times 100\% \\ &= \left( \frac{0.0036765}{0.0036765 + 1} \right) \times 100\% \\ &= 0.3663\%\end{aligned}$$

Fractional abundance is a simple expression of isotope abundance, very similar to at.%, and is used to express isotopic abundance in ppm:

$$\begin{aligned}\text{For example, ppm } ^2\text{H of standard water} \\ &= \left( \frac{^2\text{H}/^1\text{H}}{^2\text{H}/^1\text{H} + 1} \right) \times 10^6 \text{ ppm} \\ &= \left( \frac{0.00015576}{0.00015576 + 1} \right) \times 10^6 \text{ ppm} \\ &= 155.74 \text{ ppm}\end{aligned}$$

## Relative Isotope Ratio

Natural abundance measurements often require measurements of absolute variations in the third or fourth decimal place of an at.% measurement. It is, therefore, better to use a relative measurement where the sample isotopic composition is compared to an international standard in terms of per mil (‰) versus an international standard:

$$\begin{aligned}\delta (\text{‰}) &= \left( \frac{R_{\text{sample}} - R_{\text{reference}}}{R_{\text{reference}}} \right) \times 1000\text{‰} \\ &= \left( \frac{R_{\text{sample}}}{R_{\text{reference}}} - 1 \right) \times 1000\text{‰}\end{aligned}$$

where  $R$  is the absolute ratio of the heavy and light isotopes and it follows that all international standards have a delta value of 0‰ as their ratios cancel out.

In practice, an instrument records the ratio of two signals corresponding to the two isotopes,  $Rm$ .

For example

$$Rm \text{ of CO}_2 = \frac{\text{Minor Beam}}{\text{Major Beam}} = \frac{m/z \text{ 45}}{m/z \text{ 44}}$$

The 'raw' delta value of the sample is given by

$$\delta_{\text{sample(raw)}} = \left( \frac{Rm_{\text{sample}}}{Rm_{\text{reference}}} - 1 \right) \times 1000\text{‰}$$

Reference materials are used to calibrate appropriate 'working standards' that are used in individual laboratories for routine analyses. On most occasions the reference material is not an international standard but will have a known delta value ( $\delta_{\text{reference}}$ ). However, all values measured relative to the working standard must be reported relative to the primary standard. The true delta value of the sample is then given by

$$\begin{aligned}\delta_{\text{sample(true)}} &= \delta_{\text{sample (raw)}} + \delta_{\text{reference}} \\ &\quad + \left( \frac{\delta_{\text{sample (raw)}} \times \delta_{\text{reference}}}{1000} \right) \times 1000\end{aligned}$$

It is possible to rearrange this equation to deduce absolute ratios in terms of at.% and fractional isotope abundance.

The primary standards for the five major elements in the biosphere are standard mean ocean water (SMOW) for hydrogen and oxygen, Pee Dee belemnite (PDB) for carbon (and sometimes oxygen), atmospheric air for nitrogen and Canyon Diablo troilite (CDT) for sulfur (Table 1). Supplies of both SMOW and PDB have been exhausted and replaced by reference materials that have been calibrated against the original standards, available from the International Atomic Energy Agency (IAEA), Vienna, Austria. To note this change relative isotopic measurements should now be reported as versus VPDB or VSMOW ('V' for Vienna). PDB is a carbonate mineral and since chemical processes discriminate against  $^{13}\text{C}$  the vast majority of organic compounds are depleted in  $^{13}\text{C}$  versus VPDB. Hence, a number of suitable reference materials are now available, e.g., polyethylene foil (PEF1  $\delta^{13}\text{C} = -31.77\text{‰}$  versus VPDB) and sucrose (Sucrose ANU  $\delta^{13}\text{C} = -10.47\text{‰}$  versus VPDB). Similarly, because of the huge variation in  $^2\text{H}/^1\text{H}$  in global precipitation further reference materials have been made available including; Greenland ice sheet precipitation (GISP,  $\delta\text{D} = -189.5\text{‰}$  versus VSMOW) and standard light Antarctic precipitation (SLAP,  $\delta\text{D} = -428\text{‰}$  versus VSMOW).

## Mass Spectrometry

The ability to determine isotopic abundances is a main feature of MS. Even with low-resolution instruments the presence of isotopes of known natural

**Table 1** The primary standards for the five major elements in the biosphere

Element	Natural abundance (at.%)	International standard	Ratio of standard	<i>m/z</i> Ratio measured

abundance makes possible a method for deducing the elemental composition of many ions derived from organic compounds. The isotopic abundance of the elements can be classified into three general categories: 'A' those elements with only one natural isotope in appreciable abundance, 'A + 1' those elements with two natural isotopes the second of which is 1 Da heavier than the most abundant, and 'A + 2', those elements that have an isotope 2 Da heavier than the major isotope. The presence of elements in an ion is often easily recognized from the 'isotopic cluster' produced in the spectrum. For example, the presence of 1.1% <sup>13</sup>C contributes to the ion 1 Da heavier than the molecular ion. Increasing the number of carbon atoms in the ion increases the probability that one of these atoms will be a <sup>13</sup>C isotope. A C<sub>10</sub> ion will, therefore, contribute  $10 \times 1.1\% = 11\%$ . This fact allows the number of carbon atoms to be deduced. When interpreting organic mass spectra the natural variation in <sup>13</sup>C content of organic compounds is generally ignored, as is the contribution from the abundance of <sup>2</sup>H, <sup>15</sup>N, and <sup>17</sup>O.

High-precision IRMS for the determination of variations in isotope abundance was described by Nier in 1940. The essential components of the instrument remain largely unchanged to the present day. IRMS instruments are highly specialized for the analysis of <sup>13</sup>C/<sup>12</sup>C, <sup>2</sup>H/<sup>1</sup>H, <sup>15</sup>N/<sup>14</sup>N, <sup>18</sup>O/<sup>16</sup>O, and <sup>34</sup>S/<sup>32</sup>S via analysis of gases CO<sub>2</sub>, H<sub>2</sub>, N<sub>2</sub>, CO, and SO<sub>2</sub> using a tight electron ionization ion source, high transmission magnetic sector, and multiple collectors, delivering relative standard deviations of less than 0.01%. The use of multiple Faraday cup collectors, as opposed to a single electron multiplier, leads to reduced sensitivity but greatly enhanced precision. An essential feature of instruments designed for precise measurement of relative isotope ratios is a system that admits gas to the ion source, through a capillary leak, from a dual inlet or continuous flow. This permits the rapid and repeated comparisons of sample and reference gases.

Organic forms of an element can be converted directly to a gaseous form by modified Dumas combustion in evacuated sealed tubes using copper(II) oxide as the oxygen donor (reactions [I] and [II]), requiring ~10 µg to 1 mg of sample for combustion followed by N<sub>2</sub> or CO<sub>2</sub> transfer to the MS:

Alternatively, an inorganic form of the element can be conveniently converted to the desired gaseous form. A standard method for preparing CO<sub>2</sub> is the controlled reaction of carbonate with phosphoric acid (reaction [III]):

Oxygen isotope ratios may be directly measured as CO<sub>2</sub> when produced by acid reaction with carbonate or as CO when a compound is pyrolyzed. Water samples are commonly analyzed for <sup>18</sup>O/<sup>16</sup>O by equilibration with a headspace of CO<sub>2</sub>.

When measuring <sup>13</sup>C/<sup>12</sup>C ratios of CO<sub>2</sub> it is necessary to correct the interference from the isobaric ion at *m/z* 45 corresponding to <sup>12</sup>C<sup>17</sup>O<sup>16</sup>O. This is achieved by measuring *m/z* 46 (<sup>12</sup>C<sup>18</sup>O<sup>16</sup>O), since the abundance of <sup>18</sup>O may be used to correct the 45/44 ratio. The formation of HCO<sub>2</sub><sup>+</sup> from CO<sub>2</sub> and background H<sub>2</sub>O in IRMS is also troublesome because it is not resolved from <sup>13</sup>CO<sub>2</sub><sup>+</sup> and the resulting artificial enhancement of *m/z* 45 can cause systematic errors.

## Continuous Flow Mass Spectrometry Techniques

The introduction of continuous flow techniques to IRMS instrumentation permits a wide range of samples to be analyzed by highly automated systems

and has heralded a huge expansion in the use of stable isotopes in biomedical and environmental sciences. Continuous flow isotope ratio mass spectrometry (CF-IRMS) minimizes sample preparation and reduces the sample size requirements and time for the determination of carbon and nitrogen. In the most common configuration of CF-IRMS an elemental analyzer is coupled to the MS via an open-split. Using modified Dumas combustion samples are converted to  $N_2$  and  $CO_2$ , which are separated by gas chromatography (GC) and sequentially introduced to the IRMS allowing both  $\delta^{15}N$  and  $\delta^{13}C$  to be measured from a single aliquot of sample.

Online oxygen and deuterium isotope ratio determinations for organic and inorganic substances are now possible through high-temperature conversion to  $H_2$  and  $CO$  gases. Samples are pyrolytically decomposed at temperatures up to  $1450^\circ C$  in the presence of chromium or nickelized graphite. Gas/liquid equilibrators have automated H and O isotopic analysis of water in untreated aqueous fluids as complex as urine. Automated cryogenic concentrators permit analysis at ppm concentrations in environmental samples.

The development of GC coupled via a combustion furnace to an IRMS (GC-C-IRMS) has allowed the analysis of individual compounds occurring at trace levels in very complex mixtures. Sometimes referred to as compound specific isotope analysis or isotope ratio monitoring MS (GC-irmMS), this technique has opened new fields of research in areas such as organic geochemistry, food science, medicine, nutrition, sport, forensic science, archaeology, soil science, and extraterrestrial science. The chromatographic separation in connection with the combustion of the analyte, however, exerts the strongest influence on the uncertainty of the measurement. Multidimensional GC (GC/GC) has also been coupled to IRMS for the authentication of flavor components.

Since GC is limited to the analysis of volatile substances, liquid chromatography has been coupled to an IRMS allowing the analysis of high molecular weight, polar, and thermally labile materials. Because of its technical complexity this technique has found only limited use to date.

## 'Inorganic' Isotopes

Inorganic MS methods are widely used for the determination of isotope ratio measurements in an extensive range of materials, e.g., conducting, semiconducting, and nonconducting solid samples, water, organic solvents, and solutions.

Traditionally, isotope ratios have been determined using thermal ionization MS (TIMS) and to some extent glow discharge MS (GDMS). TIMS and GDMS use high-resolution mass analyzers but differ in analyte ionization methods. TIMS uses electrons from a hot filament, whereas GDMS uses direct atomization and ionization via cathodic sputtering of the sample surface in a low-pressure argon atmosphere. The GD ion source is highly efficient and is capable of measuring 99% of the elements in the periodic table. Its chief limitation is that samples must conduct electricity. TIMS can be used in negative or positive ion modes with high sensitivity and precision for a broad range of isotopes. However, time-consuming sample preparation and sample determination processes limit the applications for routine analysis.

The development of plasma source MS has enabled the determination of isotope ratio composition of metallic solid samples without requiring sample purification and has effectively replaced TIMS and GDMS in many areas. Plasma source MS uses an Ar inductively coupled plasma (ICP) as an ionization device. The quadrupole ICP-MS is less precise than TIMS but is a popular method for isotope ratio determination because of its speed and convenience. Samples may be introduced as solutions, slurries, or suspensions of very fine particles generated by laser ablation and nearly complete analytical coverage of the periodic table is available. Sample matrices, memory effects, and some instrument parameters, however, may affect the accuracy and precision of isotope ratio determinations if adequate precautions are not taken. A new generation of ICP-MS instruments using high-resolution mass analyzers now provides better sensitivity and precision than quadrupole ICP-MS. The most significant instrument improvement for isotope analysis by sector field ICP-MS has been the application of multiple ion collection devices (MC-ICP-MS) to achieve better precision of isotope ratio measurements. MC-ICP-MS is used for the precise measurement of variations in the isotopic composition of a wide range of elements and diverse applications include measurement of radiogenic and stable isotope ratios and the determination of trace element concentrations by isotope dilution.

Secondary ion MS (SIMS) employs an energetic primary ion beam of  $Ga^+$ ,  $Cs^+$ , or  $O^-$  for analyte ionization. SIMS can determine isotope ratios in intact solid samples without destroying them but has poorer resolution and sensitivity than TIMS and is difficult to standardize for biological samples. The instrument is often termed an 'ion microprobe', because it can display images showing the distribution

of specific masses on a specimen with sub-micrometer spatial resolution. SIMS is a widely used analytical method with demonstrated applications in forensic science but is being superseded by laser ablation ICP-MS (LA-ICP-MS), which provides excellent sensitivity, precision, and good accuracy for isotope ratio measurements.

Both ICP-MS and LA-ICP-MS are increasingly replacing other MS techniques that have been dominant analytical methods for precise isotope ratio measurements for many decades. For all types of inorganic IRMS, however, precision and accuracy are primarily limited by sample preparation, introduction, and analytical methodology.

## Radioisotopes

The majority of isotopes of the elements are unstable with respect to other nuclides, and spontaneously transform to more stable nuclides. These unstable species are referred to as radionuclides or radioisotopes. Two key applications of isotope ratio measurements to radioisotopes are the characterization of fissionable materials and radiocarbon dating.

The reaction between atmospheric  $^{14}\text{N}$  nuclei and cosmic rays (neutrons) produces the radionuclide  $^{14}\text{C}$ , accompanied by the emission of a proton.  $^{14}\text{C}$  produced in this manner enters the Earth's carbon cycle from which some carbon may be trapped in a form that ceases to exchange with atmospheric carbon (e.g., as rocks or plant material). As  $^{14}\text{C}$  has a half-life of 5730 years, the determination of the  $^{14}\text{C}$  to ( $^{12}\text{C} + ^{13}\text{C}$ ) ratio has become a useful technique for estimating the age of objects from 1000 to 10 000 years timescale. The  $^{14}\text{C}/^{12}\text{C}$  ratio of the atmosphere is only  $1.2 \times 10^{-12}$  and determination of this ratio requires the use of accelerator mass spectrometry (AMS). AMS utilizes a type of mass spectrometer with a van der Graaff electrostatic accelerator to accelerate negative ions produced in a SIMS or FAB type ion source at MV potentials. The ions are stripped of electrons at the terminal of the accelerator to destroy molecules isobaric with the isotope being analyzed and then reaccelerated as positive ions. The high-energy positive atomic ions are then separated using magnets and velocity filters followed by identification of the total energy and energy loss of each ion as it is individually counted in the detector. AMS can measure isotope ratios as low as  $1:10^{-14}$  with precision better than 1% and is applied to the minor isotopes of other elements such as  $^{10}\text{Be}/^9\text{Be}$ ,  $^3\text{H}/^1\text{H}$ , or  $^{36}\text{Cl}/^{35}\text{Cl}$ . AMS can also reduce the degree of radioisotope labeling required for

medical studies to measure the amount of chemical substance absorbed, distributed and eliminated from various parts of the body.

## Other Analytical Techniques

Although spectroscopic methods are far less precise than IRMS for isotope ratio measurements, they can have advantages in terms of costs and ease of operation. These techniques also remove the laborious chemical preparation required for conventional IRMS. They are most commonly applied to the analysis of samples that are artificially enriched in the heavier isotopes of nitrogen, carbon, and oxygen.

Atomic emission spectroscopy may be used to distinguish different isotopic species, e.g.,  $^{14}\text{N}^{14}\text{N}$ ,  $^{14}\text{N}^{15}\text{N}$ , and  $^{15}\text{N}^{15}\text{N}$ , present in a low-pressure gas. The sample molecules are excited by an external microwave energy source and emit ultraviolet electromagnetic radiation at specific wavelengths: 297.7, 298.3, and 298.9 nm, corresponding to the nitrogen isotopomers above. Ratios of the intensities at these wavelengths are related to the isotopic composition of the nitrogen sample.

Direct infrared laser absorption spectroscopy has been applied to low-pressure gas-phase water samples for the accurate, simultaneous determination of the relative  $^2\text{H}/^1\text{H}$ ,  $^{17}\text{O}/^{16}\text{O}$ , and  $^{18}\text{O}/^{16}\text{O}$  isotope abundance ratios of water in highly enriched samples, as used in the biomedical doubly labeled water method to quantify energy metabolism. In contrast, photoacoustic spectroscopy has also been applied to isotope ratio measurements of  $^{18}\text{O}/^{16}\text{O}$  in water vapor samples using a pulsed tuneable dye laser to provide a transportable system for *in situ* and rapid measurements in the environment.

Both nondispersive infrared spectroscopy and cavity ring down spectroscopy (employing a near-infrared external cavity diode laser) can be used to determine the  $^{13}\text{C}/^{12}\text{C}$  ratio in the  $\text{CO}_2$  of expired breath. This technique can be used to diagnose liver cirrhosis or *Helicobacter pylori* infection after feeding  $^{13}\text{C}$  labeled substrates to patients.

Laser absorption spectroscopy may also be applied to the analysis of heavy elements. For example, the isotopes of  $^{235}\text{U}$  and  $^{238}\text{U}$  may be simultaneously measured by absorption in laser-induced plasma using two separate diode lasers tuned to the absorption lines of  $^{235}\text{U}$  and  $^{238}\text{U}$ . Using this technique uranium-containing minerals may be probed directly without any preceding preparation steps.

Whilst IRMS and spectroscopic techniques precisely measure the overall isotopic content of a

molecular species, the determination of  $^2\text{H}/^1\text{H}$  and  $^{13}\text{C}/^{12}\text{C}$  ratios at each atomic site of a pure substance can be performed by site-specific natural isotope fractionation NMR spectroscopy (SNIF-NMR). The isotopic pattern of a given molecule is a rich source of information on reaction pathways and on genealogy of the atoms, on the relative rates of certain reaction steps, on the percentage of intra- and intermolecular hydrogen transfer, and possibly on the stereospecificity of reactions. The disadvantage of the technique arises from the fact that the sample must be very pure (95–100%) and since deuterium is a relatively insensitive nucleus and is present in low abundance, relatively large sample sizes and long experiment times are required. In addition, deuterium NMR spectra are not well resolved and quantification of overlapping peaks can be problematic.

Natural abundance isotope ratios provide powerful analytical criteria for authenticating the origins of products. Used alone or in combination with IRMS the SNIF-NMR technique has been used for many years for determining geographical origin, adulteration, and authenticity of many natural products (wine, tobacco, fruit juice, etc.). For example, the site-specific  $^2\text{H}$  abundance of the methyl and methylene sites of ethanol present in alcoholic drinks, determined by SNIF-NMR, may be used to infer meteorological parameters associated with the growing period and evaporation processes in casks during the aging period.

## Applications

One of the major uses of isotopically labeled molecules is as tracers for chemically similar nonlabeled compounds to follow the behavior of organic molecules in complex media such as living organisms and ecosystems. Isotope labeling provides many methods to study mineral metabolism in humans, ranging from relatively simple measurements of absorption, and fecal excretion, to complex studies using multicompartmental modeling. Most studies use highly enriched stable isotope tracers administered intravenously and/or orally, coupled with precise measurements of the resulting isotopic enrichment in blood, urine, or feces. The use of illicit drugs such as testosterone can now be detected by isotope ratio analysis when referenced against endogenous steroids.

Researchers have used isotope ratio measurements to study animal migrations, for example, by analyzing wing membranes from migratory butterflies. The isotopic composition of the wing membrane does not change after they are formed at the breeding site and provides a good marker of geographical origin.

Stable isotopes are now increasingly used for the control of the origin or authenticity of food products. For example, the  $^{13}\text{C}$  content of sugars indicates the photosynthetic metabolism of the plant that synthesized them; the deuterium content is more characteristic of secondary metabolism and of environmental factors. SNIF-NMR has been used in conjunction with stable carbon IRMS to detect sugars that have been added to monofloral honey from C4 plants (cane or corn). A comparison of the  $^{13}\text{C}$  stable isotope composition of sparkling wines and the  $\text{CO}_2$  bubbles produced by secondary fermentation from a number of countries has also been used to estimate the addition of sugar. The determination of Sr isotope ratio  $^{87}\text{Sr}/^{86}\text{Sr}$  in table and fortified wines has provided a fingerprint of wine origin for regions of France and Portugal. Despite the high complexity of seized heroin samples, determinations of the  $^{13}\text{C}/^{12}\text{C}$  and  $^{15}\text{N}/^{14}\text{N}$  ratios by IRMS provide information for the determination of their origin.

Different chemical processes lead to isotopic fractionation in the generation of petroleum. IRMS analysis can, in many cases, distinguish petroleum derived from different geographical locations that are otherwise identical. The carbon and hydrogen isotopic composition of individual compounds in crude oil or refined products provide an isotopic fingerprint for use in correlation studies and do not appear to undergo significant isotopic fractionation as a result of weathering.

The advent of laser ablation MC-ICP-MS technology allows the rapid *in situ* determination of the stable isotope ratios of heavy metals commonly found in sulfide ore deposits (e.g., Cu, Zn, Fe, Sb, Ag) providing important information on the source, transport, and depositional mechanisms of these metals.  $^{206}\text{Pb}$ ,  $^{207}\text{Pb}$ , and  $^{208}\text{Pb}$  are formed as the end product of radioactive decay and the isotopic variability of lead results because the elements from which the isotopes form were not evenly distributed in ore bodies. Hence, the analysis of stable lead isotopes in annually laminated lake-sediments is a useful method to study lead pollution history as the relative contribution of pollution and natural lead in sediment samples can be calculated. The analysis of lead isotopes by SIMS has also been used to identify the geographical origin of bullets.

The thermodynamic properties of isotopic substances are well described and oxygen isotopes are known to be sensitive tracers of climatic change, as  $\text{H}_2^{16}\text{O}$  is more readily evaporated from the ocean than its  $\text{H}_2^{18}\text{O}$  counterpart. During periods of cool climate or mini 'ice-ages' the easily evaporated  $\text{H}_2^{16}\text{O}$  is trapped on land in the form of ice or other

reservoirs changing the  $^{18}\text{O}/^{16}\text{O}$  ratio of the ocean. This record is preserved in ice cores and in the calcium carbonate shells of fossil plankton and has been used since the 1940s for the reconstruction of past climates by oxygen isotope paleothermometry.

## Introduction

There are many areas in analytical chemistry in which kinetics play a significant role. This is true not only for reaction chemistry in solution, in separation processes, and diffusion controlled methods, but also for physical excitation. All analytical methods where measurements are influenced by the occurrence of a transient (kinetic) process could therefore strictly be considered a kinetic method.

In a narrower sense, however, the term ‘kinetic method’ is confined to methods based on direct or indirect measurements of the rate of a chemical reaction, which ought to be called ‘reaction-rate methods’. This view is followed in this article.

In the next section, the general principles of the analytical use of reaction-rate methods are described; in the subsequent sections the application of non-catalytic and catalytic techniques are treated. Several methods, instruments, and techniques for which separate entries can be found in this encyclopedia are only briefly mentioned, e.g., enzymatic catalysis, chemiluminescence, sensors, data processing.

## General Considerations

Signal measurements made under dynamic conditions on systems approaching equilibrium compete in

efficiency with static and equilibrium measurements. Inasmuch as not all reactions meet the requirements imposed by static measurements, the choice is usually dictated by the specific problem addressed since there are no instrumental limitations for avoiding kinetic methodologies. Thus, kinetic determinations based on catalytic (whether enzymatic or nonenzymatic) and differential reaction-rate methods are by now well established.

The development of kinetic methods can essentially be ascribed to (1) the increasingly frequent need to quantify minute amounts (occasionally of a few nanograms or even less) of substances contained in high-purity materials or samples of environmental or biological interest, (2) the increasing knowledge available on reaction mechanisms, and (3) recent breakthroughs in instrumentation, particularly with regards to automation and computerization capabilities.

Kinetic methods have been classified according to a number of criteria. One classification distinguishes between catalytic and noncatalytic methods (see **Table 1**). The former are further divided according to the type of reaction involved, while the latter are categorized according to whether they are used to determine a single species or several components in mixtures (differential reaction-rate methods)

**Table 1** General classification of kinetic methods of analysis

### *Catalytic*

Nonenzymatic (homogeneous)  
Enzymatic (homogeneous and heterogeneous involving immobilized enzymes)  
Electrochemical (heterogeneous)

### *Noncatalytic*

For determination of a single species  
For determination of multicomponents (differential reaction-rate methods)

although this occasionally may deal with catalyst mixtures. Other possible classifications are dealt with in the pertinent sections.

The principles behind kinetic methods are described below on the basis of uncatalyzed reactions in homogeneous solutions. The rate at which a given chemical reaction develops depends on several factors including temperature, reactant concentrations, the presence or absence of catalysts, activators, and inhibitors, and dielectric constant or ionic strength. Most of the reactions employed in kinetic analysis are influenced by temperature, which usually accelerates reaction development. Hence, a thermostating device is typically needed for kinetic applications.

Kinetic methods are usually associated with two types of reactions, namely slow reactions (those with half-lives of 10 s or longer) and fast reactions (those reaching half-completion in less than 10 s), which dictate both the sample-reagent mixing procedure and the instrumentation to be used.

## Theoretical Background

### Reaction Rate and Kinetic Equations

The determination of a given species using a kinetic method based on direct or indirect measurements of its reaction rate entails monitoring changes in the reactant or product concentration. The reaction rate is defined as the number of moles of substance that is consumed or formed per unit volume per unit time. Thus, for a straightforward reaction of the type

the rate at time  $t$  will be given by

$$\text{Rate} = d[P]/dt = -d[A]/dt = -d[B]/dt \quad [1]$$

where the derivatives of  $[A]$  and  $[B]$  are negative because both species disappear as the reaction develops. The reaction rate is proportional to the concentrations of all the species that take part in the reaction and the kinetic equation for the above reaction can be written as

$$\text{Rate} = d[P]/dt = k[A][B] \quad [2]$$

where  $k$  is the so-called rate constant and denotes the reaction rate per unit concentration of reactants. The sum of exponents of  $[A]$  and  $[B]$  in eqn [2] is known as reaction order; thus reaction [1] is second order. Also, the individual exponents of  $[A]$  and  $[B]$  in eqn [2] denote their respective partial reaction orders.

If one of the reactants (e.g.,  $B$ ) is present in a large excess (over 50-fold) with respect to the other, then

its concentration changes will be negligible relative to the other. In such a case,  $[B]$  can be included in constant  $k$  in eqn [2] and the reaction assumed to be pseudo-first order in  $A$  or pseudo-zero order in  $B$ , i.e.,

$$\text{Rate} = d[P]/dt = k_A[A] \quad [3]$$

where  $k_A$  is the pseudo-first-order rate constant.

In applying most kinetic methods, experimental parameters are usually set so as to ensure pseudo-first-order reaction conditions, which is why only this type of reaction is dealt with here for simplicity.

The concentrations in eqn [1] can be replaced with any measurable quantity  $R$  provided it is directly proportional to concentration. Temporal changes in the reactant or product concentrations can be monitored physically or chemically. Physicochemical techniques (e.g., those based on absorbance, potential, temperature, luminescence, and conductivity measurements) are more commonly used for this purpose. Figure 1 shows the variation of a measured property,  $R$  (a signal), as a function of time. The reaction rate is given by the slope of the rising exponential curve at each point.

Most kinetic methods are applied to the initial portion of the curve, i.e., when the reaction has only developed by 1–3%. Such a portion is usually linear and its slope proportional to the concentration of the measured species (initial-rate methods).

### Determination of Partial Reaction Orders and Rate Constants

Reaction orders and the rate constant are typically determined experimentally under preset, controlled conditions. Establishing the kinetic or rate equation

**Figure 1** Typical kinetic curve showing the initial straight portion.

of a chemical system entails determining the partial reaction orders in the variables that influence the system. This can be done in two ways, depending on whether the rate equation is to be expressed in integral or differential form. As a rule, differential methods, which involve measuring the initial reaction rate, are usually employed for determining partial orders, whereas integral methods are preferentially used for calculating rate constants.

Differential methods rely on the assumption that, for a partial reaction order  $n$ , the initial rate is related to the concentration by

$$\text{Rate} = \tan \alpha = -d[A]/dt = k_A[A]^n \quad [4]$$

where A is the species whose partial reaction order is to be determined and  $k_A$  its pseudo- $n$ th-order rate constant.

Equation [4] can be expressed in logarithmic form as

$$\log(\tan \alpha) = \log k_A + n \log[A] \quad [5]$$

which is the equation of a straight line of slope  $n$  and intercept  $\log k_A$ . Therefore, one can obtain the partial order in A and its reaction rate from the slope and intercept, respectively, of a  $\log(\tan \alpha)$  versus  $\log[A]$  plot.

The determination of the rate constant by use of integration methods involves plotting the integral form of the kinetic equation for an assumed reaction order. Thus, the integral rate equation for a hypothetical first-order reaction is

$$\ln[A]_t = \ln[A]_0 - k_A t \quad [6]$$

where  $[A]_t$  is the concentration of species A at reaction time  $t$ ,  $[A]_0$  the initial concentration of this species, and  $k_A$  its rate constant which coincides with the slope of this plot. If, for instance, the reaction concerned is monitored photometrically via the product P, then

$$\ln(D_\infty - D_t) = \ln D_\infty - k_A t \quad [7]$$

since  $[A]_t = [P]_\infty - [P]_t$  and  $[A]_0 = [P]_\infty$ , i.e.,  $[P]$  and  $D$  (the absorbance) are proportional.

Once the influence of each variable and the concentration on the reaction rate has been determined, the kinetic equation can be formulated according to the general form

$$\nu = \text{rate} = d[P]/dt = k[A]^a[B]^b[C]^c \quad [8]$$

where P is the reaction product through which the reaction is monitored and  $k$  the rate constant, and superscripts denote the partial reaction orders in the species to which they refer.

The partial order in a given reactant will be unity if a plot of initial rate versus reactant concentration is a straight line; in fact, at  $n = 1$ , eqn [4] is representative of a straight line of zero intercept.

## Kinetic Determination of a Single Species

Inasmuch as most chemical kinetic systems involve bimolecular reactions and orders above two are a rare and analytically unusable, kinetic methods for the determination of a single species can be classified according to the kinetic order of the bimolecular reaction  $A + B \rightarrow P$  into (1) differential or pseudo-zero-order methods, and (2) integral, first-order, or pseudo-first-order methods.

### Differential Methods

Differential kinetic methods for the determination of a single species rely on measurements made at the start of reaction, i.e. when changes in the reactant or product concentrations are still negligible and hence the reaction rate is not influenced by the concentration of either reactant, so eqn [2] can be simplified to a pseudo zero-order expression

$$\text{Initial rate} = \nu_0 = d[P]/dt \approx k[A]_0[B]_0 \approx \text{constant} \quad [9]$$

which is the starting point for application of the initial-rate method. Since  $[B]_0$  is constant, a plot of the initial rate against  $[A]_0$  must be a straight line that can be used as a calibration plot for determining  $[A]_0$  from eqn [9] in incremental form, i.e.,

$$\nu_0 = \Delta[P]/\Delta t = k_A[A]_0 \quad [10]$$

Both the fixed-time and the variable-time differential methods are based on eqn [10] by making  $\Delta t$  or  $\Delta[P]$  constant, respectively. Therefore,  $[A]_0$  will be linearly related to  $\Delta t$  (or  $\Delta[P]$ ), which allows one to construct the pertinent calibration graph.

### Integral Methods

Determinations of single species by integral methods are based on the use of the integrated pseudo-first-order eqn [6] or [7], both of which allow  $[A]_0$  to be calculated from the intercept of the curve obtained by plotting  $\ln[A]_t$  as a function of time.

Application of the fixed-time and variable-time integral methods relies on eqn [6] in the form

$$\ln[A]_1/[A]_2 = k_A \Delta t \quad [11]$$

and requires that  $t_1 = 0$  (and hence  $[A]_t = [A]_0$ ) and keeping  $\Delta t$  and  $\Delta[A]$  constant, respectively.

## Kinetic Determination of Multicomponents

Differential reaction-rate methods are based on the different rate at which two or more species react with a common reagent and allow the determination of several components without the need for a prior separation.

Let A and B be two substances in a mixture that react with a reagent R to yield two products P and P', which, though different in nature, are essentially similar as regards the analytical property to be measured. If the reaction rates of the two substances are different and independent of each other, and correspond to first-order kinetics in each mixture component (i.e.,  $[R]_0 > [A]_0$  and  $[R]_0 > [B]_0$ ), then the sum of the concentrations of A and B at time  $t$  will be given by

$$\begin{aligned} C_t &= [A]_t + [B]_t = [P]_\infty - [P]_t \\ &= [A]_0 \exp(-k_A t) + [B]_0 \exp(-k_B t) \end{aligned} \quad [12]$$

where  $k_A$  and  $k_B$  are the pseudo-first-order reaction rate constants for A and B, respectively.

There are several types of differential kinetic methods and the most frequently used of which are the logarithmic-extrapolation and the proportional-equation methods, both of which are based on the application of eqn [12].

The logarithmic extrapolation method involves taking logarithms in eqn [12] and plotting  $\log C$  or  $\log([P]_\infty - [P]_t)$  as a function of time (Figure 2). The result is a curve unless  $k_A = k_B$ , in which case a straight line is obtained. If species A disappears at a higher rate than does B (i.e.,  $k_A > k_B$ ), then  $[A]_t \rightarrow 0$  and the curve eventually becomes a straight line

**Figure 2** Application of the logarithmic-extrapolation method to first-order reactions.

(Figure 2); so

$$\log C_t = \log([P]_\infty - [P]_t) = \log[B]_0 - k_B t / 2.303 \quad [13]$$

The intercept of the  $\log C_t$  or  $\log([P]_\infty - [P]_t)$  versus  $t$  plot allows the initial concentration of B,  $[B]_0$ , to be calculated, whereas that of the other component,  $[A]_0$ , can be obtained by difference once  $[A]_0 + [B]_0$  has been obtained from  $[P]$ . If a photometric technique is used for measurements, eqn [13] can be alternatively written as

$$\log(D_\infty - D_t) = \log \varepsilon_B t [B]_0 - k_B t / 2.303 \quad [14]$$

where  $D_\infty$  and  $D_t$  are the absorbances measured after the reaction has developed to completion and after a time  $t$  close to the start of the linear segment of the curve, respectively, and  $\varepsilon_B$  denotes the molar absorptivity of B, which should be known beforehand. The path length of the photometric cell is assumed to be 1 cm.

This method requires no prior knowledge of the rate constants of A or B; however, it does require at least 99% of the more reactive species to be consumed in the process if reliable results are to be obtained, and the total initial concentrations of A and B to be accurately known.

Application of the proportional-equation method to a binary mixture entails measuring  $C_t$  at two reaction times and formulating two equations similar to [12], the resolution of which provides the initial concentration of the two components as a function of their respective rate constants, which should be known in advance. Not only time, but any other experimental variable such as the temperature or one of the physicochemical properties of the reactants are usable for this purpose. The two equations in question will be of the form

$$f_1 = k_{A,1} [A]_0 k_{B,1} [B]_0 \quad [15]$$

$$f_2 = k_{A,2} [A]_0 k_{B,2} [B]_0 \quad [16]$$

where  $f$  denotes a measurable parameter determined under two different sets of experimental conditions, and  $k_{A,1}$ ,  $k_{A,2}$ ,  $k_{B,1}$ , and  $k_{B,2}$  are empirical or proportionality constants obtained separately for components A and B under different conditions.

For these methods to be applicable in practice, the rate-constant ratio,  $k_A/k_B$ , should generally be at least 3–4. However, novel mathematical approaches such as the multipoint curve-fitting method, which takes full advantage of the information provided by the entire kinetic curve (e.g., the Kalman filter), are applicable to ratios of only 1.5–2.

## Instrumentation

The present status of kinetic methods, which are currently competitive with static (equilibrium) methods in many respects, has been chiefly reached thanks to recent breakthroughs in instrumentation that have enabled their automated implementation. Electronics and computers have played decisive roles in this context as they have solved the typical problems encountered in measuring reaction time accurately – particularly in relation to fast processes – by allowing automated acquisition of data throughout.

Kinetic methods call for no measurements of absolute values of the parameter typically used to monitor reactions (absorbance, fluorescence intensity, potential), but rather for their temporal variations; as a result, kinetic measurements are free from the effects of factors that introduce errors in absolute values (e.g., turbidity, the liquid–liquid junction potential, and the presence of other absorbing or fluorescent substances provided they do not take part in the reaction of interest or alter the parameter response). However, strict timing and temperature control (to within 0.01–0.1°C) are essential to kinetic methods, which thus require modern, powerful instrumentation.

The choice of a given method for measuring the rate of a reaction is dictated by its half-life. Thus, the instrumentation required to monitor slow reactions is typically simpler than that needed for fast reactions.

### Primary Components of Kinetic Instrumentation

Kinetic methods use variously complex instruments from conventional straightforward systems such as spectrophotometers, spectrofluorimeters, or potentiometers to highly sophisticated setups, e.g., fully automatic instruments capable of collecting samples, transferring them to the detector, and transducing and processing the results obtained.

The process involved in measuring the rate of a reaction comprises the following stages:

(1) Preparation, measurement, transport, and mixing of reactants. These preliminary operations are common to other analytical methods and are a key step in kinetic methods as regards measurement of the parameter by which the process is monitored.

(2) Signal monitoring and transducing at a constant temperature, both of which are effected by the measuring instrument (e.g., photometer, potentiometer), which follows the course of the reaction concerned by measuring changes in a property of one reactant or product.

(3) Timed acquisition of data (viz., collection of signals at different times), which are processed

simultaneously or sequentially, either by manual computation or with the aid of a computer.

Fully automated systems execute all three stages above, whereas partly automated instruments usually perform stages (2) and (3) only, and process data in a sequential rather than simultaneous manner.

Each of the above stages is related to one of the basic elements of the instrumentation typically used in kinetic methods. In fact, the first stage, i.e., mixing of sample and reagents, is done differently depending on whether the external experimental conditions will remain unchanged (closed systems) or not (open systems).

### Temperature Control

Strict temperature control is compulsory at stages (1) and (2), whichever type of system is used, because fluctuations in this parameter detract from the accuracy and precision of the results. A change in the temperature by as little as 1°C may result in a variation in the reaction rate by up to 10% in some cases.

There are basically two ways of controlling the temperature: by circulating a liquid kept at a constant temperature (e.g., from a thermostatic bath) and by electrical heating (or cooling) via the Peltier effect.

### Mixing of Reactants

The manner in which reactants are mixed to start the analytical reaction depends on the type of system concerned.

**Closed and open systems** While closed systems are unsuitable for fast reactions, open systems are especially suited, so much so that they have significantly eased the use of kinetic procedures.

The sample must be thoroughly mixed with the reagent(s) at a constant temperature before it is transferred to the detection system for measurement. This can be done manually, which is usually the case with closed systems, or automatically. Automated mixing of sample and reagents calls for special mechanical devices when fast reactions, which require the use of open systems as noted earlier, are to be addressed. On the other hand, manual mixing can be accomplished by simply homogenizing the reactants in the reaction vessel, which can be a spectrophotometric cuvette or an electrode cell. The instant at which the last reactant is added is taken as the reaction start time ( $t = 0$ ) and must therefore be determined highly accurately. Alternatively, the reactants can be incorporated into the measuring system automatically in order to increase the reproducibility and throughput of closed or batch systems.

The open systems more commonly used can be classified into continuous or flow systems and discrete or batch systems (Table 2). The most popular and widely employed methods in connection with such systems for kinetic-based determinations in routine analyses are stopped-flow, stat, and continuous-addition-of-reagent methods.

**Stopped-flow methods** This type of method essentially mixes a sample solution and the reagent(s) by means of two driving syringes that are actuated manually or automatically (by a pneumatic device in the latter case) into a flow cell or mixing chamber that can also act as the observation cell. The flow is stopped abruptly by using a third syringe and the analytical signal is then recorded as a function of time. This type of method is mandatory in dealing with fast reactions with half-lives of a few milliseconds to several seconds. Its performance relies heavily on the dead time, the length of which is determined by the mixing efficiency (viz., the mixing time) and the transport and stop times. For practical

purposes, the dead time of the instrument used should be smaller than the half-life of the reaction to be addressed by approximately two orders of magnitude. Some European and American manufacturers market specific instruments and accessories including stopped-flow mixing modules that can be fitted to commercially available spectrophotometers and spectrofluorimeters for implementation of the stopped-flow technique.

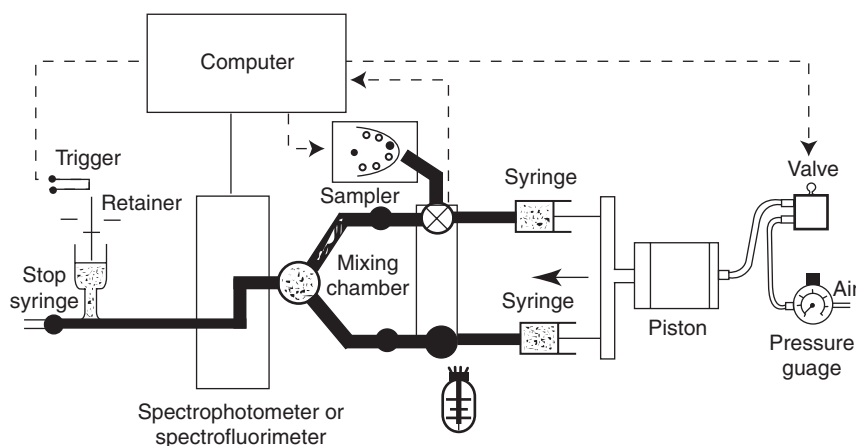

Figure 3 shows a schematic diagram of a stopped-flow spectrophotometer (or spectrofluorimeter) coupled to an automatic analyzer controlled by a computer that also handles data acquisition and processing.?

**Stat methods** Stat methods, which are suitable for slow reactions, involve addition of a reactant to the reaction vessel at a given rate such that a characteristic property of the monitored reaction is maintained constant. In practice, a small amount of one of the reaction ingredients is added until a given value of the monitored parameter (pH, absorbance, luminescence, etc.) is reached. Any deviation from this state as a result of the reaction developing further is immediately compensated for by automatically adding an extra amount of the ingredient in question. The rate of addition is used to measure the reaction rate. This type of method has so far been chiefly used quantitatively with catalyzed (including enzymatic) reactions.

**Continuous-addition-of-reagent methods** In continuous-addition-of-reagent (CAR) methods, a reagent is added at a constant rate to the species of interest and the kinetic graph (absorbance or fluorescence as a function of time) is recorded simultaneously with the aid of an automatic, computer-controlled system. A CAR system typically consists of (1) an addition unit composed of an autoburette, a fan stirrer, and a thermostatted vessel as reaction cell, (2) a photometric

(or fluorimetric) detection unit including an immersion probe for optical signal measurements, and (3) a computer. **Figure 4** shows a block diagram of the instrumental components.

The CAR technique is a major alternative to the stopped-flow technique in tackling direct rate measurements on reactions with half-lives of a few milliseconds as it requires no sophisticated instrumentation and is specially suited to routine analyses. In addition, it allows mixtures of two or more analytes to be resolved. For a binary mixture, the response versus time graph typically obtained shows two consecutive linear segments of different slope from which each reaction rate can be determined and related to the concentration of each component.

### Detection Systems

Although the course of a reaction can be monitored by chemical or even visual means, most kinetic methods rely on instruments for this purpose, optical (photometric and fluorimetric) and electroanalytical devices being by far the most common choices. In this context, it is worth emphasizing the ability of stopped-flow mixing methodology to boost the performance of the chemiluminescence reaction to which it is specially suited on account of the fast transient nature of chemiluminescence reactions.

In selecting a given instrument for a specific purpose, the user should take into account the nature of the analyte, the most suitable species for measuring its concentration, and the type of reaction involved and its half-life. Also, the response time should be short enough for the signal to be as close as possible in time to the event that gives rise to it, especially with fast reactions or initial-rate methods.

**Ultraviolet–visible molecular absorption spectrometers** This type of instrument owes much of its popularity to the availability of a large number of

reactions involving substances that absorb in the near-ultraviolet or visible region. Spectrophotometric sensing, unlike fluorimetric detection, allows the simultaneous recording of absorbance readings from the unknown sample and a blank by using a dual-beam spectrophotometer which is of special significance to monitoring development of the catalyzed reaction against the uncatalyzed reaction. However, this procedure is inadvisable for fast reactions as it may provide delayed responses that would detract from the precision of measurements.

Rapid scanning spectrometry offers an appealing potential for kinetic methods of analysis. The associated instrumentation is based on various operational principles; thus, the vidicon image detector bears some relationship to television, while photodiode array detectors consist of a very large number (a few hundreds or thousands) of individual detectors, each of which deals with a narrow band of the transmitted spectrum. Diode array systems allow the simultaneous kinetic determination of two or more dissolved species giving rise to as many reactions with the same or different reagents. Provided the species in question absorb at different wavelengths, direct resolution of the mixture only requires simultaneously measuring the initial rates at the corresponding maximum absorption wavelengths using spectrophotometers equipped with diode array detectors. **Figure 5** shows the three-dimensional plot obtained for the products afforded in the reactions of hydrazine and phenylhydrazine with p-dimethylaminobenzaldehyde (DAB) and their respective kinetic curves, which were processed simultaneously by using a computerized initial-rate method. This methodological principle has also been used in molecular fluorescence spectroscopy and kinetic fluorimetric determinations.

**Potentiometric and amperometric detectors** Potentiometric sensing usually entails the use of the variable-time approach, i.e., measuring the time elapsed until the required change between two pre-set potentials has occurred.

Selective electrodes are of special use in potentiometric techniques as applied to kinetic analysis on account of their usually high sensitivity to concentration changes. The glass (pH) electrode is very frequently used to determine enzymes and their substrates, which take part in reactions that typically involve release or uptake of hydrogen ions. The ammonia-selective membrane electrode has also been used for enzymatic analyses.

Such amperometric electrodes as the oxygen electrode are also frequently employed in enzymatic analyses involving consumption or release of oxygen

or hydrogen peroxide. The widespread usage of these electrodes is partly a result of advances in enzyme immobilization techniques. In their simplest form, these electrodes are composed of a membrane that accommodates an artificial enzyme fixed onto the transducer. The substrate diffuses across the thin catalyst layer and yields an electroactive substance that is sensed potentiometrically or amperometrically. Potentiometric sensing is more economical and easier to implement as regards the electrode preparation, albeit rather slow compared to amperometric detection, which also surpasses the former in linear range. Differential potentiometry and biamperometry are also commonplace in kinetic analyses.

### Data Acquisition and Processing

This final stage of the analytical process is a key to obtaining acceptable results, particularly in dealing with fast reactions and in differential kinetic analysis. Generated signal/time data pairs are converted into reaction rates or, directly, into analyte concentrations. How this final operation is performed depends on the nature of the applied method.

Kinetic methods for the determination of a single species can be classified into various categories according to the type of data processing system used (see Table 3).

Direct-computation methods, on which most kinetic analyzers rely, use one or more signal readouts to calculate generally the sought reaction rate.

**Table 3** Classification of kinetic methods according to data acquisition and processing

<i>Direct computation methods</i>
One-point methods
Two-point methods
Multipoint (regression) methods
<i>Curve-fitting methods</i>
Linear responses
Nonlinear responses

Depending on the number of measurements used, these methods can be further divided into one-, two-, and multipoint methods. Multipoint regression methods employ a mathematical algorithm to ensure the best possible fit between three or more data points by using a given mathematical function that coincides with the equation of a straight line for calculation of the reaction rate and hence should be fitted to the linear portion of the kinetic curve.

Until recently, a vast majority of kinetic procedures relied on direct computation methods. However, there is a current trend to increasing usage of curve-fitting methods, which compute parameter values that represent the best fit of some mathematical models to signal/time data in order to obtain the analyte concentration, the rate constant, and even the partial reaction orders. Although least-squares methods have been used most frequently for this purpose, other curve-fitting approaches such as the Kalman filter, a recursive algorithm that allows data processing in real time, are gradually gaining ground in this context.

Data acquisition by a computer-controlled instrument requires the two components to be appropriately interfaced. Analog interfaces convert a voltage or any other analog output into a binary (digital) form that can be managed by the computer. The wide availability and present affordability of computers makes this formerly complicated operation quite easy.

Recent advances in instrumentation and data acquisition and processing have put kinetic methods of analysis in prominence by virtue of their simplicity, rapidity, and precision, in addition to their ready automation for use in routine analyses.

## Introduction

Noncatalytic reactions are less frequently used in kinetic-based determinations than are those involving a catalytic effect. However, recent advances in instrumentation mean that noncatalytic kinetic methods are powerful alternatives to equilibrium (nonkinetic) methods. This type of reaction is of especial relevance to the analysis of mixtures of closely related compounds, for which a number of differential reaction rate methods have been developed. Whether for individual or joint determinations of species, the main field of application of noncatalytic reactions is organic analysis, unlike catalytic reactions, where a metal ion usually acts as the catalyst; this has also contributed to their current wide acceptance.

## Principles of Methods

Analytical methods based on noncatalytic reactions are useful for both the kinetic determination of a

single species and the simultaneous kinetic determination of several species in a mixture with no prior separation. The kinetic determination of a single species in a mixture is a special instance of the latter. These concepts are classified in Table 1 and discussed in detail below.

### Determination of a Single Species: Classical Methods

Consider a chemical species A that reacts with a reagent B to yield product P:

The determination of species A can involve two limiting situations: (1) if B is in large excess (over 50-fold) relative to the analyte (A), then the reaction will be pseudo-first order in A; (2) if the concentration of B is similar to or less than 50 times that of A, the reaction will be second order.

**Pseudo-first-order reactions** The rate of a reaction of pseudo-first order in the analyte, A, is given by

$$\text{rate} = -d[A]/dt = d[P]/dt = k[A][B]_0 = k'[A] \quad [1]$$

where  $k' = k[B]_0$ . This expression is normally the basis for the kinetic determination of A. For initial-rate

Data acquisition by a computer-controlled instrument requires the two components to be appropriately interfaced. Analog interfaces convert a voltage or any other analog output into a binary (digital) form that can be managed by the computer. The wide availability and present affordability of computers makes this formerly complicated operation quite easy.

Recent advances in instrumentation and data acquisition and processing have put kinetic methods of analysis in prominence by virtue of their simplicity, rapidity, and precision, in addition to their ready automation for use in routine analyses.

## Introduction

Noncatalytic reactions are less frequently used in kinetic-based determinations than are those involving a catalytic effect. However, recent advances in instrumentation mean that noncatalytic kinetic methods are powerful alternatives to equilibrium (nonkinetic) methods. This type of reaction is of especial relevance to the analysis of mixtures of closely related compounds, for which a number of differential reaction rate methods have been developed. Whether for individual or joint determinations of species, the main field of application of noncatalytic reactions is organic analysis, unlike catalytic reactions, where a metal ion usually acts as the catalyst; this has also contributed to their current wide acceptance.

## Principles of Methods

Analytical methods based on noncatalytic reactions are useful for both the kinetic determination of a

single species and the simultaneous kinetic determination of several species in a mixture with no prior separation. The kinetic determination of a single species in a mixture is a special instance of the latter. These concepts are classified in Table 1 and discussed in detail below.

### Determination of a Single Species: Classical Methods

Consider a chemical species A that reacts with a reagent B to yield product P:

The determination of species A can involve two limiting situations: (1) if B is in large excess (over 50-fold) relative to the analyte (A), then the reaction will be pseudo-first order in A; (2) if the concentration of B is similar to or less than 50 times that of A, the reaction will be second order.

**Pseudo-first-order reactions** The rate of a reaction of pseudo-first order in the analyte, A, is given by

$$\text{rate} = -d[A]/dt = d[P]/dt = k[A][B]_0 = k'[A] \quad [1]$$

where  $k' = k[B]_0$ . This expression is normally the basis for the kinetic determination of A. For initial-rate

methods, eqn [1] can be expressed in incremental form as

$$\text{rate} = -\Delta[A]/\Delta t = k[A]_0 \quad [2]$$

from which the concentration of A can be calculated readily (Figure 1A).

The mathematical treatments used by the fixed-time and variable-time methods rely on the exponential version of eqn [1], namely

$$\text{rate} = -d[A]/dt = k[A]_0 \exp(-kt) \quad [3]$$

Taking into account the fact that  $t_2 = \Delta t + t_1$ , integration of this equation over an interval  $t_2 - t_1$  yields

$$[A]_0 = -\Delta[A]/\exp(-kt_1)[1 - \exp(-k\Delta t)] \quad [4]$$

Application of the fixed-time method involves keeping  $t_1$  and  $\Delta t$  constant, and so, according to eqn [4],  $\Delta[A]$  and  $[A]_0$  will be linearly related (Figure 1B). Using the variable-time method (Figure 1C) involves keeping  $\Delta[A]$  constant. Since  $\Delta t$  and  $t_1$  depend on  $[A]_0$  according to eqn [4],  $[A]_0$  will never be linearly related to  $1/\Delta t$ . In this case the minimum error will be made when  $[A]_1$  is virtually identical with  $[A]_0$  and hence  $\exp(-kt_1) \rightarrow 1$ , and at short reaction times (small  $\Delta[A]$  and  $\Delta t \rightarrow 0$ ) eqn [4] can be linearized since  $(1 - \exp(-k\Delta t))$  can be simplified to  $k\Delta t$  by expanding the exponential function as a Maclaurin series. In summary, the fixed-time method

provides wider dynamic ranges than does the variable-time method for first-order or pseudo-first-order reactions (see Figures 1B and 1C).

**Second-order reactions** The rate of a second-order reaction is dependent on the concentrations of two reactants. The rate of reaction [I] is

$$\text{rate} = -d[A]/dt = -d[B]/dt = d[P]/dt = k[A][B] \quad [5]$$

If the concentrations of the two reactants are equal, then  $[A]_0 = [B]_0$ , and so eqn [5] simplifies to

$$\text{rate} = -d[A]/dt = k[A]^2 \quad [6]$$

Integration of this equation between times zero and  $t$  yields the following linear equation:

$$1/[A]_t = (1/[A]_0) + kt \quad [7]$$

from which the concentration of A can be calculated readily (Figure 2A).

For a second-order reaction in which the concentrations of the two reactants are different, integration of eqn [5] over an interval from  $t_1 = 0$  to  $t_2 = t$  leads to the general second-order integrated rate equation:

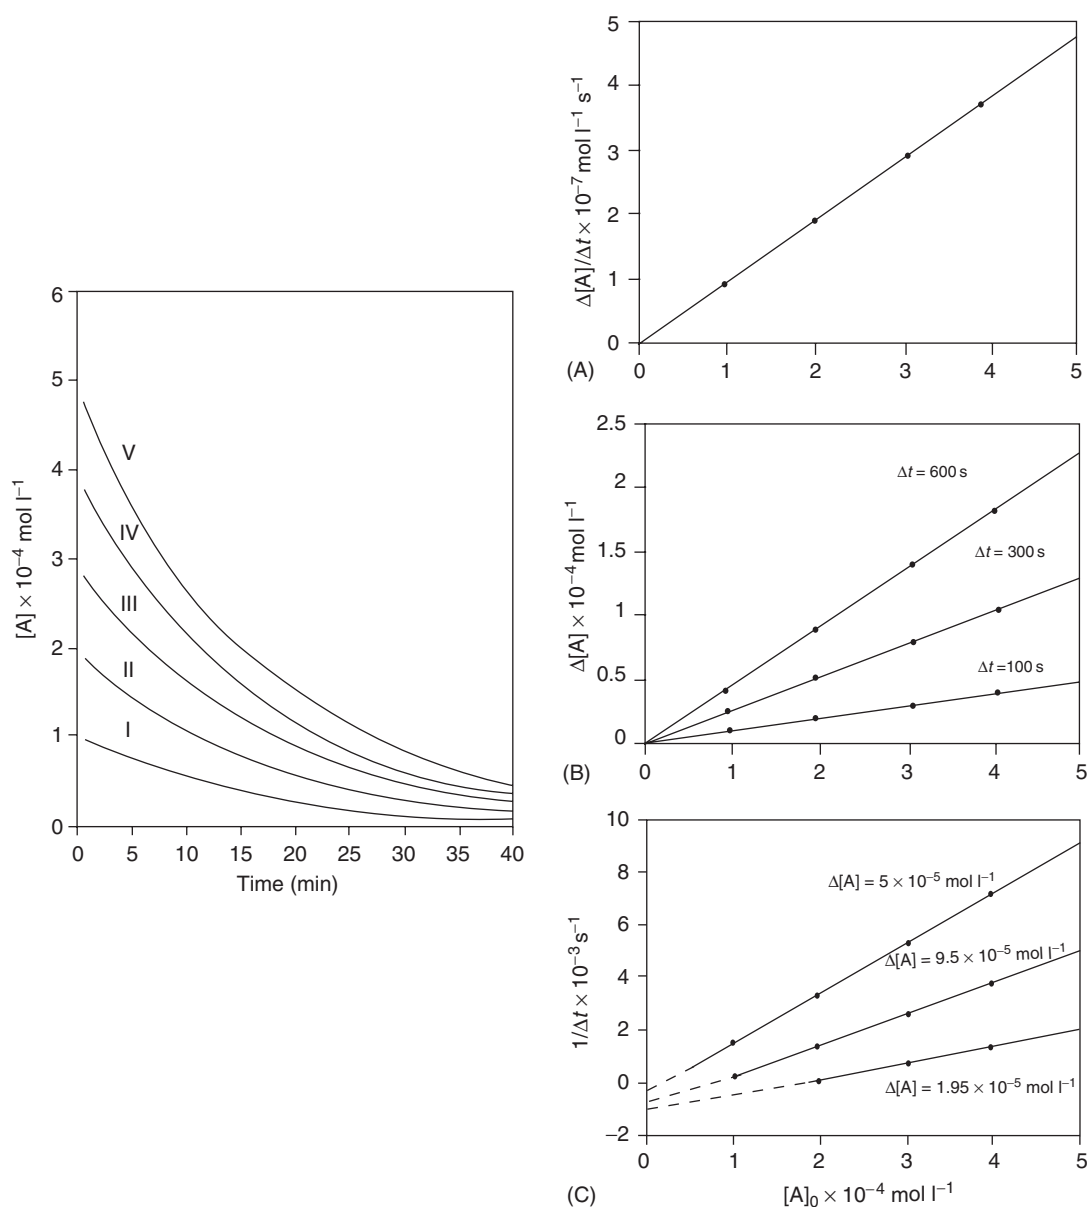

$$\ln([B]_t/[A]_t) = \ln([B]_0/[A]_0) + ([B]_0 - [A]_0)kt \quad [8]$$

A plot of  $\ln([B]_t/[A]_t)$  against time (Figure 2B) will thus provide an intercept from which the concentration of A can be calculated since  $[B]_0$  is known.

### Determination of a Single Species: Multipoint Methods

The high processing power of affordable computers has fostered the development of a variety of improved methods relying on efficient use of analytical information. These include curve-fitting methods, predictive methods, and error-compensated methods. Curve-fitting methods compute signals in order to obtain the best fit for a mathematical model describing the transient signal. A least-squares procedure is commonly used for this purpose. Predictive methods use a large number of data to obtain the best estimate for the signal change to be expected if the system is allowed to reach equilibrium. Error-compensated methods reduce the marked dependence of experimental variables in methods based on time-dependent signals. Such dependence can be minimized by using mathematical algorithms or simultaneously measuring the analytical signals and the variable(s) by which they can be affected in order to establish pertinent corrections.

**Figure 1** Kinetic profiles (left) and determination of a single species based on pseudo-first-order reactions. (A) Initial rate, (B) fixed-time, and (C) variable-time methods. Curves I–V in the kinetic profiles correspond to  $1\text{--}5 \times 10^{-4} \text{ mol l}^{-1}$ , respectively. Simulated data for  $k = 10^{-3} \text{ s}^{-1}$ .

### Determination of a Single Species in a Mixture

For the case where different chemical species in a mixture have different rates of reaction with a reagent, it is possible to treat each species separately. That means that during a certain time interval only one of the species has to be considered because the other species have already reacted or react so slowly that they do not interfere with the rate measurements. The criteria for neglecting reactions of slower or faster reacting components are the ratio of their rate constants, the ratio of their concentrations, and the time interval of measurement.

Consider the determination of A in the presence of B. Their respective integrated first-order rate equations will be

$$\ln([A]_0/[A]_t) = k_A(t - t_0) \quad \ln([B]_0/[B]_t) = k_B(t - t_0) \quad [9]$$

If the extent of reaction of B over the interval from  $t_0$  to  $t$  is short enough, then  $[A]_0$  can be determined readily by simply measuring  $[A]_t$ . However, if B reacts to an appreciable extent, the degree of interference with the analyte reaction can be calculated from the ratio of the two above expressions.

**Figure 2** Determination of a single species based on second-order reactions. (A) Identical reactant concentrations; and (B) unequal reactant concentrations. Simulated data for  $[A]_0 = 10^{-3} \text{ mol l}^{-1}$ ,  $[B]_0 = 5.0 \times 10^{-3} \text{ mol l}^{-1}$ , and  $k = 10^2 \text{ mol l}^{-1} \text{ s}^{-1}$ .

Thus

$$\ln([A]_0/[A]_t)/\ln([B]_0/[B]_t) = k_A/k_B \quad [10]$$

This equation is time dependent and relates the extent of both reactions to their rate constants. If a maximum error of 1% is considered to be acceptable (i.e., if there is still 1% of A present when less than 1% of B has reacted), the  $k_A/k_B$  ratio in eqn [10] should be  $\approx 500$ . (This follows from  $\log 100/\log 1.01 = 463$ .)

The error made in calculating  $[A]_0$  from a given rate constant ratio at a given extent of reaction will be

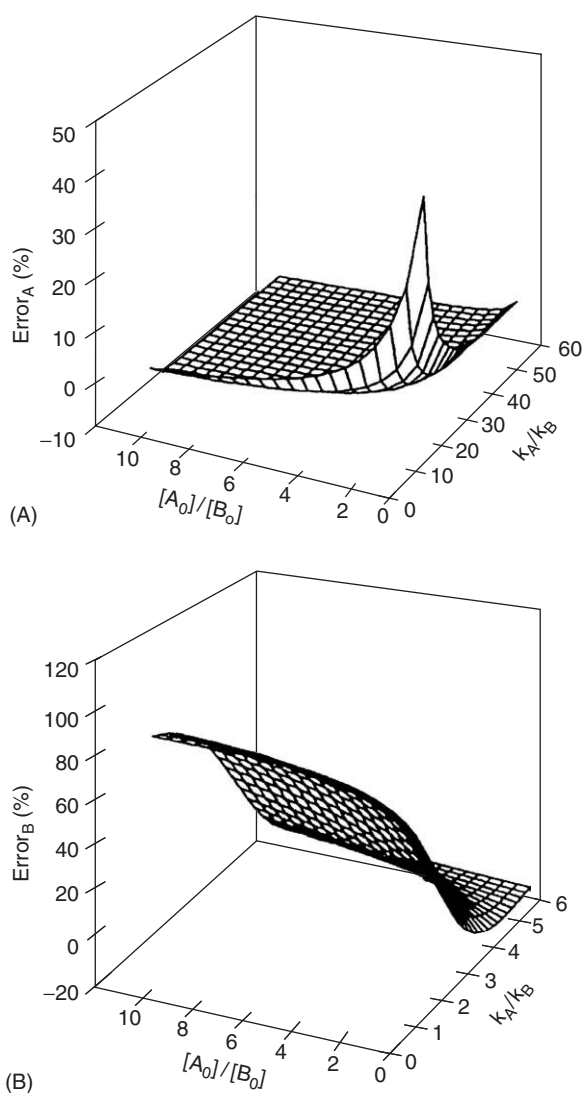

$$\begin{aligned} \%e_A &= \frac{[P_B]_t}{([P_A]_t + [P_B]_t)} \times 100 \\ &= \frac{[B]_0[1 - \exp(-k_B t)]}{[A]_0[1 - \exp(-k_A t)] + [B]_0[1 - \exp(-k_B t)]} \times 100 \end{aligned} \quad [11]$$

where  $[P_A]_t$  and  $[P_B]_t$  are the concentrations of the products formed at time  $t$ . **Figure 3A** is a 3D plot of  $\%error_A$  as a function of  $k_A/k_B$  and  $[A]_0/[B]_0$ . As can be seen, the error made in the determination decreases with increasing rate constant ratio and increasing  $[A]_0/[B]_0$ .

The error made in the determination of B can be calculated from

$$\begin{aligned} \%e_B &= \frac{[A]_t}{([A]_t + [B]_t)} \times 100 \\ &= \frac{[A]_0[1 - \exp(-k_A t)]}{[A]_0[1 - \exp(-k_A t)] + [B]_0[1 - \exp(-k_B t)]} \times 100 \end{aligned} \quad [12]$$

**Figure 3B** is a similar 3D plot for  $\%error_B$ . As can be seen, the relative error decreases with increasing rate constant ratio and increasing concentration of B in the mixture.

**Figure 3** Variation of the relative error in the determination of (A) reactant A in a mixture with B and (B) reactant B in a mixture with A, as a function of  $[A]_0/[B]_0$  and  $k_A/k_B$ . Simulated data at 60 s reaction time.

### Simultaneous Kinetic-Based Determinations

Multideterminations of species are of great interest to kinetic methods of analysis. Various mathematical algorithms allow exploiting of the whole kinetic curve to determine the concentrations of two or more analytes in a mixture.

Curve-fitting methods compute the parameters that give the best fit of some mathematical model to signal-time data. Traditionally, least-squares methods have been most frequently used. The Kalman filter, however, which is one of the most powerful algorithms available for simultaneous kinetic-based determinations, allows reliable calculation of the rate constant,  $k$ , the net signal change,  $\Delta A$ , and the background contribution,  $C$ , from the following equation for a binary mixture:

$$\Delta A_t = \Delta A_A[1 - \exp(-k_A t)] + \Delta A_B[1 - \exp(k_B t)] + C \quad [13]$$

where  $A_t$  is the total absorbance at time  $t$  and  $\Delta A_A$  and  $\Delta A_B$ , and  $k_A$  and  $k_B$  are the net absorbance changes and the rate constants of A and B, respectively. It is superior to classical multicomponent methods (see first section of this topic), especially as regards the rate constant ratio of reactions for a binary mixture, which can be closer to unity than in the classical methods. Thus the Kalman filter provided satisfactory results (error less than 10%) in the resolution of mixtures of 2- and 3-chlorophenol (concentration ratio 1:4 to 4:1), where the rate constant ratio was only 1.4. Linear or nonlinear models are used to resolve mixtures, depending on whether or not the rate constants of the two reactions are accurately known.

The use of multidetection devices such as diode array systems allows the application of multivariate calibration methods. To gain selectivity both spectral and temporal domains are incorporated. The simultaneous determination of analytes is facilitated as no prior knowledge of rate constants and explicit adoption of a kinetic model are necessary.

Recently artificial neural networks have also been successfully applied. So the concentration ratio for the above-mentioned resolution of chlorophenols could be 1:9 to 9:1 with an error of 10%.

### Reaction Types

The different reaction types involved in individual and simultaneous kinetic-based determinations of species can be classified into several categories, which are described in detail below. As a rule, kinetic-based determinations of a single species have chiefly been used for organic species, whereas simultaneous

determinations have been applied to inorganic and organic species alike.

### Complexation Reactions

This group encompasses both formation and substitution reactions, both of which have mainly been applied to inorganic analysis.

**Substitution reactions** Methods based on substitution reactions can in turn be classified according to whether a ligand or a metal is displaced from the starting complex:

The ligands most frequently used in this context are aminopolycarboxylic acids, particularly 1,2-diaminocyclohexane- $N,N,N',N'$ -tetraacetic acid (DCTA) on account of the advantages deriving from the singular kinetic behavior of M-DCTA complexes, which are employed either as chelating agents or scavengers. Classical chromogenic reagents such as (4-(2'-pyridylazo)resorcinol) (PAR) and (1-(2'-pyridylazo)-2-naphthol) are often included in the starting complexes.

Binary, ternary, and even quaternary mixtures of transition metals can be resolved by ligand substitution; on the other hand, metal-substitution reactions permit the resolution of mixtures of alkaline earth metals. These determinations usually involve photometric detection thanks to the chromogenic reagents used; also, signal readings are usually processed by using the logarithmic extrapolation method and stopped-flow instrumentation is required on account of the typically short half-lives of the reactions involved.

**Complex-formation reactions** This type of reaction is mainly used for the determination of a single metal ion and is less commonly employed (together with dissociation reactions) in simultaneous kinetic-based determinations than are substitution reactions.

Regarding determinations of a single species, iron, copper, and aluminum are the metal ions most frequently determined. The reactivity of iron(II) toward ferriox-type ligands (1,10-phenanthroline, 2,2'-bipyridyl, ferrozine, etc.) is the basis for a number of methods. The special interest of aluminum can be ascribed to its fluorescent chelates, which allow the highly sensitive kinetic determination of this metal ion.

Few simultaneous kinetic methods are based on this type of reaction. One typical example is the

simultaneous analysis for nitric oxide and nitrogen dioxide in air by formation of the iron(II)–nitrosyl complexes from nitrogen oxide and nitrogen dioxide. Also, a representative example of a dissociation reaction is the decomposition of the nitrilotriacetic acid (NTA) complexes of molybdenum(VI) and tungsten(VI) by the hydroxide ion.

### Redox Reactions

This type of reaction has been used for the determination of anionic rather than cationic species in inorganic analysis. Thus, halides have been determined using their inhibitory effect on the oxidation of organic compounds by metal ions, as well as in photochemical reactions; on the other hand, the oxidizing power of some metal ions such as cerium(IV) and vanadium(V) has been exploited for their own determination. Photochemical reduction reactions have also been used for the determination of anions such as nitrate in effluents. Most of the few reported simultaneous kinetic determinations relying on redox reactions are based on the reduction of heteropoly acids formed between molybdate and silicate, phosphate, or germanate ions.

Redox reactions are of special interest in organic analysis and rely on the oxidation of organic compounds by a strong oxidant such as permanganate, periodate, or hydrogen peroxide. For example, periodate is a common oxidant for organic hydroxyl compounds including phenols, chlorophenols, and vicinal glycols (Malaprade reaction). Fixed-time (absorbance measurements) and variable-time (perchlorate ion-selective electrode) methods can be used for the determination of these species and related substances such as carbohydrates.

One interesting redox reaction is the reversible interconversion of ferriin/ferroin complexes. The 1,10-phenanthroline/iron(III) complex (ferriin) has been used to oxidize species of clinical and pharmaceutical interest such as analgesics and catecholamines, the reaction being monitored by measuring the initial rate of change of the absorbance of the ferroin formed at 510 nm. This type of reaction has also been used in simultaneous kinetic-based determinations, such as the resolution of mixtures of uric acid and ascorbic acid, paracetamol and oxyphenbutazone, and adrenaline and noradrenaline.

As a rule, these determinations use the initial reaction rate method. Their prominence in recent years can be ascribed to the increasing availability of inexpensive mixing systems such as modular stopped-flow and continuous-addition-of-reagent devices, which enable kinetic monitoring.

### Coupled Reactions

The most representative example of this type of reaction is the so-called Griess reaction, originally developed for the kinetic determination of nitrite. Nitrite in a weakly acidic solution reacts with an amine (usually sulfanilic acid) to form the corresponding diazonium salt, which then couples with a naphthylamine or naphthol. This reaction can also be used for the kinetic determination of nitrate after reduction in a column, as well as for measuring other species such as sulfonamides (Bratton–Marshall reaction), and benzodiazepines and *N*-methylcarbamate pesticides, the hydrolysis of which yields the corresponding benzophenones (which can be diazotized) and naphthols (useful for the coupling reaction), respectively.

Oxidative coupling reactions of *p*-phenylenediamines with amines and phenols are widely used. As can be seen in **Scheme 1** *p*-phenylene diamine is oxidized to its quinone diimine (QDI) by potassium hexacyanoferrate(III) or a similar oxidant in a weakly basic medium. In the rate-limiting step, QDI reacts with the amine or phenol to give leuco-indamines (indophenols), which are rapidly oxidized to colored indamines (indophenols) with the aid of a QDI molecule. This reaction is chiefly used for resolving a large variety of mixtures of aromatic amines, phenols, and chlorophenols.

Bromination reactions use bromine generated *in situ* from the  $\text{BrO}_3^-/\text{Br}^-$  couple in an acidic medium. At low analyte concentrations, the rate of bromination and bromine generation are virtually the same, and so methyl orange in the reaction medium will only be decolorized after the bromination process has been completed. The decolorization time will be proportional to the analyte concentration. Bromide can be determined in addition to phenol compounds, which are the typical substrates. Salicylic acid and paracetamol in mixtures with caffeine can also be determined this way.

### Chemiluminescence Reactions

While the main field of application of chemiluminescence (CL) reactions is catalytic processes (e.g., oxidation of luminol in the presence of metal ions), some noncatalytic reactions are also of great interest on account of the high sensitivity they provide. One of the most prominent of such reactions is that involving the hydrogen peroxide-induced oxidation of aryl oxalate esters in the presence of a suitable fluorescent species (**Scheme 2**). The most widely used aryl oxalates for this purpose are bis(2,4,6-trichlorophenyl)oxalate (TCPO) and bis(2,4-dinitrophenyl)oxalate. These CL reactions have been used

Scheme 1

Scheme 2

for liquid chromatographic detection in the determination of a great variety of fluorescent compounds by their native fluorescence (or that of a compound obtained on derivatization).

### Miscellaneous Reactions

Formation of addition compounds from species containing carbonyl groups has been exploited for the determination of organic compounds reacting with hydrogen sulfite ion in the presence of acetone, methanol, or acetic acid. Primary amines can be determined alone and in mixtures with secondary and tertiary amines by condensation with aldehydes such as salicylaldehyde and 4-dimethylaminocinnamaldehyde.

Hydrolysis reactions have also been used for individual (e.g., nitroglycerine in ethanol) and simultaneous kinetic-based determinations (e.g., penicillins and their derivatives).

The determination of the rates of methyl ketal formation in the reaction of dehydroascorbic acid

has been used to determine its content in tablets of vitamin C.

In the Fujiwara reaction chlorohydrocarbons react with pyridine (*N*-alkylation) under complete destruction of the ring. But the reaction path will go through a number of Schiff base intermediates, which, depending of the kind of analyte, have different life times and absorbances in the visible range. Thus mixtures of 1,1,1-trichloroethane, trichloroethylene, and chloroform could be resolved, even in the presence of unknown interfering substances.

### Reactions in Micellar Systems

The use of organic microheterogeneous systems for developing new or improving known kinetic-based determinations is progressing well. Many micellar kinetic determinations based on uncatalyzed reactions have involved aromatic nucleophilic substitutions, e.g., reactions between 1-fluoro-2,2-dinitrobenzene and primary and secondary amines, phenolic compounds, and thiols. These reactions

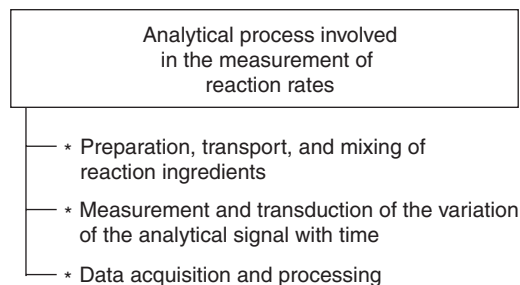

have been considerably accelerated by cationic micelles. A determination of different analytes is possible, even in turbid and colored samples, by using a fluoride ion-selective electrode. A kinetic method for the determination of hydrazine and phenylhydrazine based on their condensation with *p*-dimethylaminobenzaldehyde in anionic sodium dodecyl sulfate solutions has been described.

Very promising is the application of micelles for differential reaction rate methods. Micelles can alter the rate constant ratio of two or more species that interact with a common reagent. Simultaneous kinetic determination of nickel and cobalt based on the complex formation with 5-octyloxymethyl-8-quinolinol in the nonionic micellar medium of Triton X-100 is effective as this surfactant decreases the rates of formation of both complexes compared with an aqueous medium, so permitting their spectrophotometric monitoring. In the micellar medium the formation of the Co complex is 44 times faster than that of Ni, and determinations of both ions in the  $10^{-5}$  mol l<sup>-1</sup> range are possible.

## Methods of Monitoring Reactions

Kinetic-based determinations involving noncatalytic reactions use instruments of variable complexity for monitoring reactions. The great developments in the so-called intelligent instrumentation have fostered automation to a greater or lesser extent of the three essential steps involved in measuring reaction rates (Figure 4), the first of which is the most relevant to automation on account of the high complexity of the operations involved (complete automation of this step, however, is still impossible). Thus, the choice of the type of instrument to be used should be dictated not only by its technical features (mainly related to the second and third steps) but also by the half-life of the reaction concerned (closely related to the first step).

**Figure 4** Basic steps of reaction rate-based determinations. (Reproduced with permission from Silva M (1993) Recent strategies in automated reaction rate-based determinations. Tutorial Review. *Analyst* 118: 681–688.)

Manual mixing of sample and reagents in the reaction vessel, which may be a spectrophotometer cuvette or an electrode cell, is usually adequate for monitoring slow reactions, whether in batch or closed systems. Flow systems avoid some manipulation, and so they result in increased precision in the determinations.

Flow systems, both continuous and discrete, are used in kinetic-based determinations for monitoring fast reactions mainly. To this end (1) the dead time in the mixing system should be several orders of magnitude lower than the half-life of the reaction concerned; and (2) nearly the whole kinetic curve must be recorded in order to implement reaction rate-based determinations and perform fundamental kinetic studies (e.g., the determination of reaction orders and rate constants). The advent of stopped-flow mixing and the continuous-addition-of-reagent technique has made noncatalytic reactions competitive with equilibrium methods in practical terms.

## The Stopped-Flow Technique

The stopped-flow technique is the most commonly used for studying and implementing application of fast reactions with half-lives between a few milliseconds and a few seconds. The special features of this technique, in which reactants are driven at a high rate into a mixing and/or observation cell, the flow is abruptly stopped, and the extent of reaction monitored (Figure 5), have facilitated studies on the kinetics and mechanism of fast reactions and enabled the development of reaction rate-based determinations.

The stopped-flow technique was introduced by Chance in 1940. Earlier applications to kinetic analysis were concerned with studies on kinetics and reaction mechanisms (e.g., the formation of the iron(III)–thiocyanate complex, that of 12-molybdophosphoric acid, the redox reaction between 2,6-dichlorophenolindophenol and ascorbic acid, etc.) as well as the resolution of mixtures of metal ions using substitution reactions. On the other hand, the inception of commercially available stopped-flow instruments and inexpensive modular mixing systems for adaptation to existing detectors have led to a broad use of this technique in routine kinetic determination of individual species and mixtures in a variety of samples of clinical, pharmaceutical, nutritional, and environmental interest. The analytical features of the methods developed for this purpose usually surpass those of the equilibrium counterparts, as shown by the selected examples given in Table 2. In addition, stopped-flow systems accelerate some slow reactions relative to the conventional kinetic technique as a

**Figure 5** Typical instrumental setup used and signal–time profile provided by the stopped-flow technique. The shaded area denotes reaction development during the stop time. (Reproduced with permission from Silva M (1993) Recent strategies in automated reaction rate-based determinations. *Tutorial Review: Analyst* 118: 681–688.)

**Table 2** Selected applications illustrating the advantages of the stopped-flow technique over equilibrium methods

Analyte/chemical system	Remarks
Urea/biacetyl monoxime	Conventional equilibrium method: reaction time ~20–30 min; uses a high-temperature and a concentrated acid medium. Stopped flow: 2–3 min for acquisition of analytical data; avoids the use of drastic experimental conditions
Carbaryl/diazotized sulfanilic acid	Wider determination range; higher selectivity factors for other <i>N</i> -methylcarbamate pesticides; no blank is required for the stopped-flow technique
Psychotropic drugs/hydrogen peroxide	Addition of an oxidant is unnecessary in the stopped-flow technique since oxidation is effected by dissolved oxygen itself

result of mixing taking place at a higher pressure. Hence the stopped-flow technique can also be advantageously applied to this type of reaction, thereby saving time and reagents and simplifying handling of the reaction ingredients.

### The Continuous-Addition-of-Reagent Technique

This technique is a major alternative to the stopped-flow technique for performing rate measurements on fast reactions as it uses simpler instrumentation (Figure 4, previous article) to add the reagent (*R*) continuously at a constant rate, *u*, over a volume *V*<sub>0</sub> of sample containing the analyte (*A*). The overall reaction rate of the process, which depends on the rate of the reaction and the dilution of the species present in the reaction vessel, can be expressed in integral form as

$$\ln([A]/[A]_0) = -k[R]_0 t + (k[R]_0 V_0/u - 1)\ln(V_0 + ut/V_0) \quad [14]$$

where *[A]*<sub>0</sub> and *[A]* are the analyte concentrations at time zero and time *t*, respectively; *[R]*<sub>0</sub> is the reagent concentration in the addition unit; and *k* is the pseudo-second-order reaction rate constant. The special way in which sample and reagents are mixed in this technique allows reaction half-lives to be altered

through changes in the reagent concentration and its rate of addition.

This technique provides a full kinetic profile (Figure 6A) that can be used to implement two reaction rate methodologies, namely (1) the initial-reaction method, based on the initial concave portion of the curve, along which the analytical signal is directly proportional to *t*<sup>2</sup> and (2) the maximum-reaction method, which relies on the linear intermediate portion of the curve. Based on reported results, the maximum-reaction method is preferable. In addition, it offers several advantages over traditional pseudo-first-order initial-rate methods, particularly a much wider linear portion for measurements to be made, where instrumental errors are much smaller.

This technique is currently being used for individual and multiple determinations of species with interesting results. However, it is particularly suitable for reactions where excess reagent might have undesirable effects on the analytical signal (e.g., the determination of sulfonamides using the Bratton–Marshall reaction). Even though the kinetic profile obtained in such a case is somewhat special (Figure 6B), the maximum-reaction method can be accurate over the linear portion of the kinetic curve.

**Figure 6** Kinetic profiles provided by continuous-addition-of-reagent technique. (A) Typical kinetic curve. (B) Recording obtained for a chemical system involving an undesirable interaction between the reagent and some reaction ingredient. (Reproduced with permission from Silva M (1993) Recent strategies in automated reaction rate-based determinations. *Tutorial Review: Analyst* 118: 681–688.)

## Analytes Determined

Originally, noncatalytic reactions were seldom used for the determination of a single inorganic or organic species because equilibrium methods were faster and just as sensitive. Their use was limited to slow reactions, for which kinetic methods offer some advantages over equilibrium methods (e.g., the effect of undesirable side-reactions is avoided and analytical data are acquired in a shorter time). The above-described automated mixing devices have extended the scope of application of these kinetic-based determinations to fast reactions, especially in organic analysis. These methods make interesting alternatives to equilibrium methods for practical purposes. On the other hand, simultaneous kinetic determinations clearly outdo equilibrium methods. Classical differential methods were formerly aimed at the resolution of mixtures of inorganic species but are currently more often applied to the simultaneous determination of organic species, especially using multipoint methodologies.

### Determination of Inorganic Species

Complex-formation and redox reactions have so far been the most frequently used for the determination of both metals and nonmetals (Table 3). A variety of transition metal ions have been thus determined including such common elements as iron, copper, and calcium and rare earths as well as technetium and europium. Common nonmetals such as nitrogen anions and phosphate, bromide, and sulfur anions have also been determined this way. However, the most important applications of noncatalytic reactions in inorganic analysis are the simultaneous determinations of metal ions. As can be seen in Table 4, a wide variety of binary mixtures and some ternary and even

quaternary mixtures have been resolved using complexation reactions mainly. It is worth emphasizing the determinations of alkaline earth metals, both individually and in mixtures, which are unaffordable by methods based on catalytic reactions as the metal ions exert no catalytic effect.

The analytical features of these determinations warrant some comments. Thus, (1) photometric and potentiometric (ion-selective electrodes) techniques are widely used; (2) in many cases, determinations are nearly fully automated by using the stopped-flow technique for mixing sample and reagents; (3) determination ranges typically lie in the microgram per milliliter range except for fluorimetric detection (the limit of detection (LOD) for europium in Table 4 is  $3 \times 10^{-13} \text{ mol l}^{-1}$ ); and (4) the maximum analyte concentration ratio afforded by simultaneous methods is usually  $\sim 5:1$  but also occasionally  $10:1$  or even higher, depending on the rate constant ratio and the particular method used.

### Determination of Organic Compounds

Kinetic-based determinations involving noncatalytic reactions are quite commonly used for the determination of organic substances since these generally exhibit no catalytic properties and so they are elusive to conventional equilibrium methods. A great variety of organic compounds have been determined this way including substances possessing reducible groups or aromatic nuclei, amines, carbonyl compounds, etc. – the former, however, are the most frequently determined on account of their reactivity toward strong oxidants (Table 5). Table 6 includes some other types of reaction. Species of clinical and pharmaceutical interest such as vitamins, catecholamines, analgesics, and psychotropic drugs have been

**Table 3** Selected determinations of inorganic species using noncatalytic reactions

Analyte	Chemical system	Determination range or LOD <sup>a</sup>	Observations
Iron	Complex formation with thiocyanate	1.0–30	Iron(II; III) can be determined using SF
Copper	Complex formation with 5,5-di-methyl-1,3-cyclohexanedione bis(4-phenyl-3-thiosemicarbazone)	0.8–8	Reaction medium: 2.5–3.0 mol l <sup>-1</sup> HCl. Both fixed time and initial rate were used
Calcium	Complex formation with <i>o</i> -cresolphthalein	1.0–50	Endpoint determination using SF
Technetium	Color formation with 1,3,5-triphenyl- $\Delta^2$ -pyrazoline	0.01–12	Initial-rate and fixed-time methods used
Aluminum	Complex formation with F <sup>-</sup>		Stopped-flow technique, fluoride-selective electrode
Europium	Complex formation with 4,7-bis(chlorosulfophenyl)-1,10-phenanthroline-2,9-dicarboxylic acid	$3 \times 10^{-13}$ mol l <sup>-1</sup>	Determination using microsecond time-resolved fluorimetry
Hydrazine	Reaction with Mo(VI)	10 <sup>-3</sup> mol l <sup>-1</sup> level	Use of variable and fixed-time methods. Spectrophotometric detection
Nitrite	Griess reaction	$1.0 \times 10^{-6}$ mol l <sup>-1</sup>	SF mixing. Nitrate can be determined using cadmium
Sulfite	Reaction with Methyl Green	0.05–25	Fixed-time procedure, absorbance measurement at 625 nm
Sulfur anions	Reaction with iodate		The iodide produced is monitored using an iodide-selective electrode
Phosphate	Complex formation with Mo(VI)	20–100	The fast formation of 12-molybdo-phosphoric acid was studied using SF
Bromide	Bromination reaction	0.1–20	Chromotrope 2B can be used instead of methyl orange

<sup>a</sup>In micrograms per milliliter or as stated otherwise.  
LOD, limit of detection; SF, stopped flow.

determined regularly. As regards simultaneous kinetic determinations, early application involving simple organic compounds such as acids, alcohols, amines, and ketones have been extended to more complex substances in the environmental and clinical fields (Tables 7 and 8).

Organic kinetic-based determinations usually involve photometric or fluorimetric detection (many organic compounds and their reaction products exhibit native fluorescence). The determination levels typically achieved range from a few nanograms per milliliter to a few micrograms per milliliter but can be further lowered by using chemical and instrumental means. Examples of chemical and instrumental enhancement of these determinations are the use of micellar media for quantifying organic peroxides (Table 5) and diode array detection for measuring butylated hydroxyanisole (Table 6). Because fast reactions are quite commonplace in this context, the stopped-flow and continuous-addition-of-reagent techniques are frequently employed for mixing the sample and reagents. Finally, mixtures are usually resolved by using the classical differential reaction rate, logarithmic-extrapolation, and proportional-equation methods, even though currently multipoint

methods are interesting alternatives (e.g., for the simultaneous determination of corticosteroids using the Kalman filter algorithm, Table 7).

## Selected Applications

The use of kinetic methods of analysis based on noncatalytic reactions has leveled off in the last few years, especially as regards practical applications; in any case some of them are the best choices available to analytical chemists for individual and multicomponent determinations of species in a wide variety of real samples. This growing use of noncatalytic kinetic methods can largely be ascribed to the increased automation of reaction rate-based determinations, especially in organic analysis. Applications of these methods to real samples lie in various areas; those of environmental, clinical, pharmaceutical, and nutritional interest are discussed in some detail below on account of their great significance.

### Environmental Analysis

Noncatalytic kinetic methods have been widely applied in this area for several reasons, namely

**Table 4** Selected simultaneous determinations of inorganic species

<i>Chemical system</i>	<i>Mixtures analyzed</i>	<i>Observations</i>
M-EGTA + PAR → M-PAR + EGTA	Ni-Co, Zn-Pb, Fe-Ni, Zn-Cd, Cu-Pb, Co-Ni-Zn-Pb	Absorbance data at 500 nm are processed using the logarithmic extrapolation method. Determinations at the micromolar level
M-EGTA + BPDP → M-BPDP + EGTA	Fe(II)-Fe(III)	Progress of reaction was followed by monitoring absorbance at 556 nm
M-EDTA + PAR → M-PAR + EDTA	Ga-In	Determination in river waters
M-DCTA + Pb → Pb-DCTA + M	Mg-Ca, Sr-Ca, Sr-Ba, Mg-Ca-Sr	Determination range: $1 \times 10^{-6}$ – $5 \times 10^{-4}$ mg l <sup>-1</sup> Precision: 5–10%
M-XO + EDTA → M-EDTA + XO	La-Eu-Tb	Following the ligand replacement in a micellar solution. A partial least-squares regression algorithm was used for data processing
M + MTB	Mg-Ca	Photodiode array detection, usage of partial least-squares data analysis
X + Fe <sup>2+</sup> → Fe(X) <sup>2+</sup>	NO-NO <sub>2</sub>	Stopped-flow mixing. The samples assayed contained NO <sub>2</sub> at levels 2.3–5.5 times higher than that of NO
X + MoO <sub>4</sub> <sup>2-</sup> → heteropolymolybdates	PO <sub>4</sub> <sup>3-</sup> -SiO <sub>3</sub> <sup>2-</sup>	Use of the CAR technique. Determination at phosphate/silicate ratios from 12:1 to 1:25. Determination in sunflowers
M + PT → M-PT	Fe-Co, Ni-Co, Cu-Fe	Logarithmic-extrapolation and single-point methods Interpolation method used to overcome synergistic effects Use of the continuous-addition-of-reagent technique
M + TCSP → M-TCSP	Zn-Hg	Using the method of proportional equations in an unsegmented continuous-flow system at two different pH values
Fe(II)DGT	IO <sub>3</sub> <sup>-</sup> -IO <sub>4</sub> <sup>-</sup>	Spectrophotometric determination of the Fe(III)DGT complex at 410 nm
M-NTA + OH <sup>-</sup> → MO <sub>4</sub> <sup>2-</sup> (MO <sub>3</sub> <sup>-</sup> ) + NTA	Mo-W, Mo-V, Mo-W-V	Stopped-flow mixing with ultraviolet detection at 260 nm Determination limit: $\sim 10^{-5}$ mol l <sup>-1</sup> . RSD: 2–4%
X + F <sup>-</sup> → Fluoro complexes	Fe(III)-Zr(IV)	Use of a fluoride-selective electrode. Kalman filter algorithm
XO <sub>3</sub> <sup>-</sup> (XO <sub>4</sub> <sup>-</sup> ) + I <sup>-</sup> → I <sub>2</sub>	IO <sub>3</sub> <sup>-</sup> -BrO <sub>3</sub> <sup>-</sup> , IO <sub>4</sub> <sup>-</sup> -BrO <sub>3</sub> <sup>-</sup>	Use of a continuous-flow system and the logarithmic-extrapolation method
Luminol + K <sub>2</sub> S <sub>2</sub> O <sub>8</sub> Hydrolysis at 70°C	Au-Ag Phosphates	Time-resolved CL Resolution of pyrophosphate/tripolyphosphate mixtures in a 1.0 mol l <sup>-1</sup> HCl medium
X + DTNB	CN <sup>-</sup> -S <sup>2-</sup> -SO <sub>3</sub> <sup>2-</sup>	Application of the cationic surfactant cetyltrimethylammonium bromide. Binary mixtures may be determined in the 10 <sup>-4</sup> mol l <sup>-1</sup> range using the multiple linear regression method
XO <sub>4</sub> <sup>3-</sup> -MoO <sub>4</sub> <sup>2-</sup>	PO <sub>4</sub> <sup>3-</sup> -AsO <sub>4</sub> <sup>3-</sup>	The heteropoly acids formed will be subsequently reduced by ascorbic acid to form heteropoly blue species. Triton X-100 micelles were present
M + morin	Nb-Ta, Ga-In	Use of linear extrapolation methods and fluorescence monitoring. Detection limits of 10 <sup>-8</sup> mol l <sup>-1</sup>
M + PAR	Ln-Pr-Nd	Data obtained at multiple wavelengths over time by use of stopped-flow mixing and photodiode array detector

EGTA, ethyleneglycol bis(2-aminoethyl ether)-*N,N,N',N'*-tetraacetic acid; DTNB, 5,5'-dithiobis-(2-nitrobenzoic acid); MTB, Methylthymol Blue; PT, pyridoxal thiosemicarbazone; DGT, dipyrldylglyoxal dithiocarbazone; HMF, 3-hydroxy-7-methoxyflavone; TCSP, 5,10,15,20-tetrakis-(3-chloro-4-sulfophenyl)porphine; RSD, relative standard deviation; PAR: 4-(2'-pyridylazo)resorcinol; DCTA, 1,2-diaminocyclohexane-*N,N,N',N'* tetraacetic acid.

(1) matrixes are usually quite simple, and so they allow direct determinations; (2) environmental samples are abundant and readily available; and (3) the properties of these samples make them ideal candidates for automated analysis. Table 9 shows most of the species determined kinetically using noncatalytic reactions. As can be seen, most of the entries are

kinetic-based determinations of inorganic species in water samples.

### Clinical Analysis

Serum and urine are the two types of sample most frequently analyzed in this context. The species

**Table 5** Selected determinations of a single organic species based on redox reactions

Analyte	Reagent	Determination range or LOD <sup>a</sup>	Observations
Ascorbic acid	DPIP	$2.0 \times 10^{-7}$ – $2.0 \times 10^{-5}$	Stopped-flow mixing. Measurement time 10 s. RSD 2%
Ascorbic acid	MoO <sub>4</sub> <sup>2-</sup>	$5.0 \times 10^{-5}$ – $6.0 \times 10^{-3}$	Fixed-time spectrophotometric method. Determination in fruits and pharmaceuticals.
Tartaric acid	IO <sub>4</sub> <sup>-</sup>	$4.0 \times 10^{-7}$ – $1.2 \times 10^{-4}$	Use of a liquid-membrane periodate-selective electrode
Vicinal glycols	IO <sub>4</sub> <sup>-</sup>	$1.4 \times 10^{-3}$ – $7.0 \times 10^{-3}$	Malaprade reaction. Use of variable-time method
Catecholamines	IO <sub>4</sub> <sup>-</sup>	$2.0 \times 10^{-4}$ – $2.0 \times 10^{-2}$	Allows mixture resolution
Sucrose	IO <sub>4</sub> <sup>-</sup>	0.01–1.0	Reaction requires 30 min prehydrolysis time
Thiamine	Fe(CN) <sub>6</sub> <sup>3-</sup>	$8.3 \times 10^{-9}$ – $7.5 \times 10^{-6}$	Use of the CAR technique and fluorimetric detection
Morphine	Fe(CN) <sub>6</sub> <sup>3-</sup>	$4.5 \times 10^{-8}$ – $2.5 \times 10^{-6}$	Useful for solving a variety of medical problems
Carbamazepine	Ce(IV)	0.04–140 $\mu\text{g ml}^{-1}$	Stopped-flow mixing and fluorimetric detection
Choline	Ce(IV)	$1.0 \times 10^{-5}$ – $1.0 \times 10^{-3}$	Fluorimetric monitoring of the Ce <sup>3+</sup> formed
Ethanol	MnO <sub>4</sub> <sup>-</sup>	0.2–2.0 $\mu\text{g ml}^{-1}$	Up to a fivefold concentration of methanol is tolerated
Uric acid	H <sub>2</sub> O <sub>2</sub> /TRIAP	0.03–3 $\mu\text{g ml}^{-1}$	Stopped-flow mixing. Reactions carried out at 40°C
Acetaminophen	Ferriin	0.25–25 $\mu\text{g ml}^{-1}$	Stopped-flow mixing. A reaction mechanism is proposed
Organic peroxides	I <sub>3</sub> <sup>-</sup> /CPC	$5.0 \times 10^{-7}$ – $2.5 \times 10^{-6}$	Reaction in a micellar medium
Theophylline	Ce(IV)	$5.0 \times 10^{-5}$ – $3.5 \times 10^{-3}$	Stopped-flow procedure

<sup>a</sup> In moles per liter or as stated otherwise.DPIP, 2,6-dichlorophenol indophenol; TRIAP, 1,1,3-tricyano-2-aminoprop-1-ene; ferriin, 1,10-phenanthroline/Fe<sup>3+</sup> complex; CPC, hexadecylpyridinium chloride; CAR, continuous-addition-of-reagent; RSD, relative standard deviation.**Table 6** Selected determinations of a single organic species based on miscellaneous reactions

Analyte	Chemical system	Determination range or LOD <sup>a</sup>	Observations
Phenols	Bromination reaction	$10^{-3}$ mol l <sup>-1</sup>	Variable-time method
Primary and secondary amines	Reaction with 1-fluoro-2,4-dinitrobenzene	$10^{-4}$ – $10^{-3}$ mol l <sup>-1</sup>	A fluoride-selective electrode is used.
	Reaction with 1,2-naphthoquinone-4-sulfonate		Measurement of color formation in the presence of Triton X-100
N-Methylcarbamate pesticides	Griess reaction with 1-naphthol as coupling reagent	0.35–40	Carbaryl, carbofuran, and propoxur are determined using stopped-flow mixing
Sulfonamides	Griess reaction	0.5–8.5	Practical problems associated with these types of reaction were avoided by using the CAR technique
Benzodiazepines	Griess reaction	0.15–3.65	
Butylated hydroxyanisole	Gibbs reaction	0.5–400	Amplification method using a DA detector
Formaldehyde	Reaction with CN <sup>-</sup>	1.0–6.0	Use of an ion-selective electrode
Methemoglobin	Color formation with CN <sup>-</sup>		Curve fitting
Urea	Biacetyl + Fe <sup>3+</sup> + TSC	0.5–10	Direct determination in serum
Creatinine	Alkaline picrate	10–100	Fluorimetric detection. Stopped-flow mixing
Zineb	Zincon	0.25–30	Monitoring of the fast complex reaction using CAR
Procaine	Condensation with 1,2-naphthoquinone-4-sulfonate	1–200	Spectrophotometric detection and stopped-flow mixing
Cefadroxil	Alkaline hydrolysis	10–100 mg l <sup>-1</sup>	Absorbance measurement at 470 nm. Determination in capsules and tablets
Furazolidone, furaltadone	Alkaline hydrolysis	1–20	Use of method of tangents
Aromatic aldehydes	Condensation with barbituric acid	$5 \times 10^{-4}$ – $10^{-6}$ mol l <sup>-1</sup>	
Morphine	Reaction with 1-fluoro-2,4-dinitrobenzene	15	Potentiometric initial rate method with F <sup>-</sup> -selective electrode detection

<sup>a</sup> In micrograms per milliliter or as otherwise stated.

TSC: thiosemicarbazone; Zineb: dithiocarbamate fungicide; Zincon: 2-carboxy-2'-hydroxy-5'-sulfoformazylbenzene, DA: diode-array; CAR: continuous-addition-of-reagent.

**Table 7** Selected simultaneous determinations of organic species based on redox reactions

<i>Mixtures analyzed</i>	<i>Reagent</i>	<i>Observations</i>
Carbohydrates	$\text{IO}_4^-$	Enthalpimetric determination of glucose and fructose using a reaction cell fitted with a thermistor
Carboxylic acids	$\text{Ag}^{2+}$	Anodic oxidation of $\text{Ag}^+$ at a Pt electrode
Tartaric/formic acid	$\text{MnO}_4^-$	Second-order reactions. Mixtures of formic/tartaric acid in ratios from 1:10 to 4.5:1 can be resolved
Adrenaline/noradrenalin	$\text{Fe}(1,10\text{phen})^{3+}$	Spectrophotometric determination of the $\text{Fe}^{2+}$ complex
Paracetamol/oxyphenbutazone	$\text{Fe}(\text{bipy})^{3+}$	Spectrophotometric determination of the $\text{Fe}^{2+}$ complex
Amoxycillin/clavulanic acid	$\text{Ce}(\text{IV})$	Formation of the corresponding fluorescent derivatives. Stopped-flow mixing
Thiamine and its pyrophosphoric ester	$\text{Hg}^{2+}$	Use of the logarithmic-extrapolation method to resolve mixtures of thiamine and its pyrophosphoric ester in ratios of 4:1 to 1:15
Uric/ascorbic acid	$\text{Fe}(\text{bipy})^{3+}$	The tris(2,2'-bipyridine)iron(III) complex acts as the oxidant. A nonlinear method for estimating the mixture composition is used.
Catecholamines	$\text{IO}_4^-$	Mixtures of epinephrine and L-dopa at the micromole per liter level are resolved by formation of the corresponding aminochromes. Stopped-flow mixing
Phenothiazines	Dissolved $\text{O}_2$	Perphenazine/chlorpromazine mixtures at the micrograms per milliliter level are resolved with fluorimetric detection and stopped-flow mixing
	$\text{Fe}^{3+}$	Methotrimepazine/thioridazine mixtures of 12–88% of one component in the presence of the other can be determined with stopped-flow mixing and diode-array detection. Use of proportional equations
Corticosteroids	Blue Tetrazolium	Use of the Kalman filter algorithm to resolve mixtures of cortisone and hydrocortisone with a pseudo-first order rate constant ratio as low as 1.8 Comparison with logarithmic-extrapolation and proportional-equations methods
Ephedrine/phenylephedrine	$\text{IO}_4^-$	Use of stopped-flow mixing. Absorbance resulting from formazan formation was monitored at 620 nm. Method of proportional equations
Imipramine/desipramine	$\text{Fe}^{3+}$	Oxidative coupling with 3-methyl benzothiazoline-2-hydrazone. Initial rate measurements and change in absorbance measured after 5 min

typically determined in them, both inorganic and organic, are summarized in **Table 9**. Most of the determinations require wet or dry treatment for inorganic species and wet processing for organic compounds. Although direct determinations are occasionally possible (e.g., urea, uric acid, and phosphate in serum and urine), a separation technique is usually needed. Thus, protein precipitation is required in the determination of calcium and magnesium in serum; also Sep-Pack  $\text{C}_{18}$  cartridges are used to remove matrix interference in many determinations. The sensitivity achieved in many cases results in the rather low sample consumption (25–500  $\mu\text{l}$  for serum samples), which is of great significance to analyses in biological fluids.

### Pharmaceutical Analysis

Interest in the application of kinetic-based determinations in this area has grown steadily because

pharmaceutical samples are readily available and their matrixes are usually fairly simple. Virtually all kinds of preparations (e.g., tablets, capsules, syrups, injectables) have been assayed for a great variety of organic compounds (**Table 9**). Direct determinations are feasible in many cases.

### Food Analysis

Application of kinetic methods in this field has grown dramatically over the last few years. As can be seen from **Table 9**, the applications involve inorganic and organic species alike. The types of sample assayed are widely variable, and so no general sample treatment can be discussed. Ascorbic acid has been the organic species most frequently determined, whereas iron, nitrite, and phosphate have been the inorganic ions most commonly assayed.

**Table 8** Selected simultaneous determinations of organic species based on miscellaneous reactions

Type of reaction	Mixtures analyzed	Observations
Griess reaction	<i>N</i> -Methylcarbamate pesticides	Mixtures of carbaryl and its hydrolysis product (1-naphthol) and of carbofuran and propoxur can be resolved using the stopped-flow technique
	1- and 2-Naphthol	Mixtures in ratios from 20:1 to 1:5 were resolved as were ternary mixtures with carbaryl
Condensation	Spermine/spermidine	Mixtures in ratios of 20:1 to 1:20 were analyzed at the microgram per milliliter level. Photometric detection and stopped-flow mixing.
	Hydrazine/phenylhydrazine	Analytes reacted with <i>p</i> -dimethylaminobenzaldehyde and a diode array detector used to monitor the reaction
	Dehydroascorbic acid/ascorbic acid	Methyl ketal formation. Using fast atom bombardment mass spectrometry.
	Amino acids	Use of ninhydrin reaction. Binary or ternary mixtures from glycine, leucine, isoleucine, lysine, histidine can be resolved by using multipoint curve-fitting methods
Oxidative coupling	Cresols	Reaction with DPD/hexacyanoferrate(III). <i>o</i> -Cresol/ <i>m</i> -cresol mixtures determined at the micromoles per liter level
	Chlorophenols	Reaction with DPD/hexacyanoferrate(III). Resolution of mixtures of 2- and 3-chlorophenol, where the pseudo-first-order rate constant was only 1.4
Complex formation	Zineb/Maneb	Decomposition of dithiocarbamate-type pesticides and complexation of the released metal ion by Zincon. CAR technique with photometric detection
Hydrolysis	Penicillins	Hydrolysis reactions in an acidic medium. Mixtures of penicillins and 6-aminopenicillanic acid can be resolved.
CN group exchange	Amines	2-Hydroxybenzaldehyde azine used as reagent. Binary mixtures of hydrazine, hydroxylamine, and ammonia can be resolved. In all cases 2-hydroxybenzaldehyde hydrazone is formed, which is fluorimetrically detected
Fujiwara reaction	Chlorinated hydrocarbons	The red colored products of the reaction with the reagent (pyridine, water, base) were detected at different wavelengths using optical sensors

DPD, *N,N*-diethyl-*p*-phenylenediamine; Zineb and Maneb, dithiocarbamate fungicides; Zincon, 2-carboxy-2'-hydroxy-5'-sulfoformazyl-benzene; CAR, continuous-addition-of-reagent.

**Table 9** Some applications of kinetic noncatalytic methods

<i>Environmental analysis</i>	
Natural waters	Manganese, arsenic, magnesium, hypochlorite, silicate + phosphate, carbaryl, carbofuran, hydrazine, NTA
Wastewaters	Mercury, nitrite, benzaldehyde, formaldehyde
Sea and river waters	Calcium, aluminum, calcium + magnesium, gallium + indium, diaquat
Air	Manganese, nitrogen oxides(NO + NO <sub>2</sub> ), carbon dioxide
Others	Carbofuran (soils), carbaryl (vegetables), Zineb (vine and olive leaves)
<i>Clinical analysis</i>	
Serum	Calcium, magnesium, aluminum, copper + zinc, copper + iron, nitrate, phosphate. Creatinine, paracetamol, albumin, ascorbic acid, total serum protein, urea, uric acid, hemoglobin, methemoglobin, reduced glutathione, imipramine, desipramine
Urine	Nitrate, phosphate, ascorbic acid, sulfonamides, catecholamines, uric acid, morphine
<i>Pharmaceutical analysis</i>	
	Bismuth, ascorbic acid, tartaric acid, hydrazine and related compounds, nitroglycerine, paracetamol, sulfonamides, tetracyclines, thiamine, vitamin B <sub>12</sub> , theophiline, procaine, benzocaine, perphenazine, chlorpromazine, methotrimeprazine, thioridazine, catecholamines, oxazepam, nitrazepam, carbimazole, tobramycin, bromhexine, bromazepam, pyridoxine, amoxyllin, clavulanic acid, furazolidone, furaltadone, ephedrine, phenylephedrine
<i>Food analysis</i>	
	Calcium, magnesium, iron, tryptophan, and crude protein (animal feed), ascorbic acid (orange, lemon and tomato juice, green tea, potatoes, red pepper, spinach, and strawberry), sulfite (fruit juice), iron(II, III) (wines), nitrite (cod liver oil, cured meat), aluminum (spinach leaves, tea leaves), bromate (bread), tryptophan (vegetables and fish), butylated hydroxyanisole (sunflower, corn, and olive oil), kojic acid (fermentation broth), and sucrose (milk and soft drinks)

This article is reproduced from the first edition, pp. 2437–2449, © 1995, Elsevier Ltd., with revisions made by G Werner.

## Introduction

Catalytic techniques are more significant than non-catalytic ones in the broad scope of applications of kinetic methods due to their superior sensitivity and selectivity. The general principles behind the techniques outlined in the following sections are described in more detail elsewhere in this encyclopedia. Thus, this article is exclusively concerned with reaction rate methods of catalyzed reactions in homogeneous media. No mention is made of enzymatic analysis, which is treated elsewhere.

## Principles of Catalytic Methods

### General Considerations

Some substances including metals, nonmetals, and to some extent even organic compounds are known to accelerate slow reactions by a catalytic effect. Inasmuch as the rate of a catalyzed reaction is directly proportional to the catalyst concentration, such a reaction can be used for the determination of the

catalyst. Catalytic methods of this type are extremely sensitive since the catalyst is not consumed in the reaction but takes part in it in a cyclic manner. The fact that ‘small causes have great effects’ (e.g., on color development, luminescence) is the basis for trace and subtrace analysis using instrumental techniques. A catalyst can be defined as a substance that lowers the free activation energy of a reaction without altering its equilibrium position. The reaction that is catalyzed by the substance to be determined is known as the indicator reaction. One can find some 400 different indicator reactions in the literature for ~50 elements and numerous compounds. The rate of the blank indicator reaction must be very low or negligible relative to that of the catalyzed reaction if it is to be used for analytical purposes.

### Kinetic Equations and Reaction Mechanisms

The rate equation for a reaction

where B is in excess with respect to A and C being the catalyst is given by

$$v = -d[A]/dt = k[A][C]_0 + k_1[A] \quad [1]$$

or

$$v = d[P]/dt = (k[A]_0 - [P])[C]_0 + k_1([A]_0 - [P]) \quad [2]$$

This article is reproduced from the first edition, pp. 2437–2449, © 1995, Elsevier Ltd., with revisions made by G Werner.

## Introduction

Catalytic techniques are more significant than non-catalytic ones in the broad scope of applications of kinetic methods due to their superior sensitivity and selectivity. The general principles behind the techniques outlined in the following sections are described in more detail elsewhere in this encyclopedia. Thus, this article is exclusively concerned with reaction rate methods of catalyzed reactions in homogeneous media. No mention is made of enzymatic analysis, which is treated elsewhere.

## Principles of Catalytic Methods

### General Considerations

Some substances including metals, nonmetals, and to some extent even organic compounds are known to accelerate slow reactions by a catalytic effect. Inasmuch as the rate of a catalyzed reaction is directly proportional to the catalyst concentration, such a reaction can be used for the determination of the

catalyst. Catalytic methods of this type are extremely sensitive since the catalyst is not consumed in the reaction but takes part in it in a cyclic manner. The fact that ‘small causes have great effects’ (e.g., on color development, luminescence) is the basis for trace and subtrace analysis using instrumental techniques. A catalyst can be defined as a substance that lowers the free activation energy of a reaction without altering its equilibrium position. The reaction that is catalyzed by the substance to be determined is known as the indicator reaction. One can find some 400 different indicator reactions in the literature for ~50 elements and numerous compounds. The rate of the blank indicator reaction must be very low or negligible relative to that of the catalyzed reaction if it is to be used for analytical purposes.

### Kinetic Equations and Reaction Mechanisms

The rate equation for a reaction

where B is in excess with respect to A and C being the catalyst is given by

$$v = -d[A]/dt = k[A][C]_0 + k_1[A] \quad [1]$$

or

$$v = d[P]/dt = (k[A]_0 - [P])[C]_0 + k_1([A]_0 - [P]) \quad [2]$$

according to whether reactant A or product P is monitored,  $[A]_0$  being the initial concentration of A,  $[P]$  the concentration of product formed, and  $k$  and  $k_1$  the pseudo-first order rate constants of the catalyzed and uncatalyzed reactions, respectively. The reaction must be made pseudo-first order in the monitored reactant since the catalyst concentration, by definition, does not change during the reaction.

The rate of the indicator reaction  $A + B \rightarrow P + Y$  can be increased by the action of a catalyst C in two different ways, i.e., by forming a transient intermediate complex with one of the reactants (e.g., B) or by reaction with one of the reactants (e.g., A) to yield one of the reaction products and the activated form of the catalyst.

In the first way, the catalyst–reactant complex (CB) interacts with the other reactant (A) to yield one of the reaction products while regenerating the catalyst.

Here two different cases can be considered depending on whether the rate-determining step (RDS) is reaction [I] or [II]. The overall rate of the process depends on the relative values of the constants  $k_1$ ,  $k_{-1}$ , and  $k_2$ . As a rule, reaction [II] is the RDS (i.e.,  $k_2 < k_{-1}$ ); the complex dissociation reaction is much faster than the reaction between such a complex and reactant A, and the process is said to be in pre-equilibrium. However, in some processes (chiefly enzymatic reactions), the opposite holds, and so reaction [I] is the rds (i.e.,  $k_2 > k_{-1}$ , and  $k_2 > k_1$ ) and the concentration of CB in the reaction medium is always constant and very small, hence the term steady state. Chelate and complex formation reactions between the catalyst and the substrate are highly significant to the above catalytic cycle and the basis for a host of catalytic reactions.

The other possible way in which the catalyst may interact with the ingredients of the indicator reaction involves reacting with A to yield P and its own activated form,  $C^*$ , from which it is rapidly regenerated on subsequent reaction with B to yield Y according to the following sequence

where [III] is the RDS. Many catalytic methods are based on this type of mechanism, where the formation of species  $C^*$  involves a change in the oxidation

state of the catalyst. For this mechanism to occur, the system concerned must meet two requirements, namely (1) the oxidation potential of the catalytic system,  $E_C$ , must be more positive than that of the P/A couple and more negative than that of the B/Y couple (i.e.,  $E_{B/Y} > E_C > E_{P/A}$ ); and (2) a direct interaction between A and B, though thermodynamically permitted, must be kinetically forbidden. In addition, the reaction between the catalyst and B should be very fast.

The sum of the constituent reactions of the two mechanisms makes up the overall indicator reaction. These mechanisms are deceptively simple; in fact, each step consists of a series of stages, one of which can be the actual RDS.

### Methods of Determination

Usage of a kinetic method to determine a catalyst entails recording (normally in an automatic or semi-automatic fashion) the kinetic curve, i.e., the variation of the measured property as a function of time. Kinetic curves consist of rising or falling segments, depending on whether the monitored species is a product or reactant, respectively.

Kinetic catalytic methods for determination of species can be classified in a manner similar to that of the kinetic noncatalytic methods described elsewhere in this encyclopedia (Table 1). Methods commonly used to measure induction periods are commented on in dealing with Landolt reactions below.

**Initial-rate method** The initial-rate method assumes that  $[P]$  is negligible compared with  $[A]_0$ ; the latter can be considered to remain constant in eqn [2], which can thus be simplified to

$$v_o = d[P]/dt = \tan \alpha = \Delta[P]/\Delta t = k'[C]_0 + k'_1 \quad [3]$$

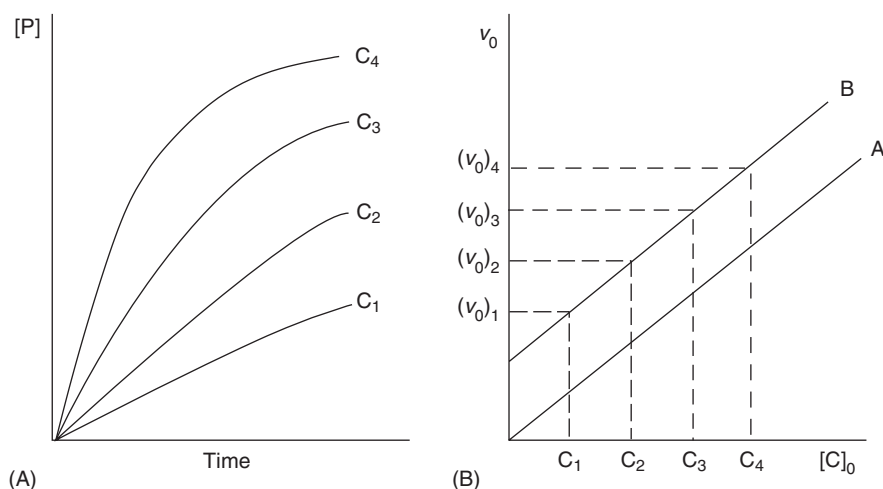

Therefore, the variation of  $[P]$  through the measured property as a function of time will be a straight segment (Figure 1A), which is the ultimate basis

**Table 1** Kinetic methods of analysis based on catalyzed reactions

*Differential*  
Initial rate  
Fixed time  
Variable time

*Integration*  
Tangent  
Fixed time  
Variable time

*Induction period measurements*

**Figure 1** Implementation of the initial-rate method. (Reproduced with permission from Pérez-Bendito D and Silva M (1988) *Kinetic Methods in Analytical Chemistry*. Chichester: Ellis Horwood.)

for this method. By plotting  $v_0$  against the catalyst concentration,  $[C]_0$ , for a series of samples containing known concentrations of the catalyst (Figure 1B) one obtains a straight line of zero (A) or nonzero intercept (B), depending on whether the uncatalyzed reaction develops to a negligible or appreciable extent, respectively.

**Differential fixed-time method** Implementation of this kinetic method involves measuring the concentration of a reactant or product at a preset time from the start of the reaction according to the following equation

$$\Delta[P] = k'[C]_0\Delta t + k_1'\Delta t \quad [4]$$

Since  $\Delta t$  is constant, plotting  $\Delta[P]$  as a function of  $[C]_0$  yields a straight line of slope  $k'\Delta t$  and intercept  $k_1'\Delta t$ , as shown in Figure 2 for  $k_1 = 0$ .

**Differential variable-time method** This method, also known as the 'fixed- or constant-concentration method', entails measuring the time required for a preset change in the reaction medium to take place. Solving eqn [4] for  $1/\Delta t$  yields

$$1/\Delta t = (k'[C]_0 + k_1')/\Delta[P] \quad [5]$$

Consequently, since  $\Delta[P]$  is constant, a plot of  $1/\Delta t$  versus  $[C]_0$  will be a straight line of slope  $k'/\Delta[P]$  and intercept  $k_1'/\Delta[P]$ , as shown in Figure 3 for  $k_1 = 0$ .

If  $[P]$  is not negligible relative to  $[A]_0$  in eqn [2], the equation must be integrated over a finite, though not necessarily short, time interval. Since integral methods are less commonly used than differential methods, they are not dealt with here.

### Catalytic Modified Effects

Catalytic determinations are based on either of the following approaches: (1) direct use of primary catalytic effects (determination of catalysts) and (2) use of modified catalytic reactions (improved determination of catalysts or determination of a modifier such as an activator or an inhibitor).

These effects, which change the rate of a catalytic reaction, are of great theoretical and practical significance. Catalytic methods are widely used in trace analysis on the grounds of their low detection limits and in some cases good selectivity. But there is always a wish to improve these figures of merit. The addition of auxiliary reagents may have these desired effects. Activators are substances that do not catalyze the indicator reaction, but their presence significantly increases the rate of the catalyzed reaction. There are several explanations for this effect, the most important being the facilitation of the catalyst-reactant interaction and the participation of the activator in the regeneration process of the catalyst.

On the other hand some substances combine with the catalyst to form some sort of a complex, which either has less catalytic activity than the free metal ion or renders the catalyst completely inactive.

As described for uncatalyzed reactions, a way to enhance the sensitivity and/or selectivity of catalytic determinations is to have the reaction develop in a micellar medium.

The rate of a metal ion-catalyzed reaction is usually modified by the presence of hydroxylated, polyaminocarboxylic, and chromogenic ligands; however, complexones are preferentially used as inhibitors, while other ligands are employed as inhibitors or activators, depending on the particular

**Figure 2** Implementation of the fixed-time method. (Reproduced with permission from Pérez-Bendito D and Silva M (1988) *Kinetic Methods in Analytical Chemistry*. Chichester: Ellis Horwood.)

**Figure 3** Implementation of the variable-time method (Reproduced with permission from Pérez-Bendito D and Silva M (1988) *Kinetic Methods in Analytical Chemistry*. Chichester: Ellis Horwood.)

needs. Inorganic anions usually act as inhibitors for these reactions, while metal ions are used both to inhibit anion-catalyzed reactions and activate metal-catalyzed reactions.

Activators and inhibitors can be determined kinetically with good sensitivity and acceptable detection limits (between  $10^{-6}$  and  $10^{-5} \text{ mol l}^{-1}$ ), though not so good as those achieved in the determination of the catalyst. The precision, however, is rather poor in many instances. Similarly, inhibitory effects allow the kinetic determination of some substances that act as inhibitors for catalyzed reactions, provided the rate of the modified reaction is proportional to the inhibitor concentration.

### Catalytic Titrations

One of the major applications of inhibitory effects lies in the determination of the inhibitor using catalytic titration. This technique combines kinetic and

equilibrium concepts into an endpoint methodology. Catalytic titrations rely on the inhibitory effect of a given substance (an anion, ligand, or metal) on a metal- or anion-catalyzed reaction and are used for the determination of not only the inhibitor but also the catalyst or other species (usually metal ions) with no catalytic or inhibitory properties such as alkaline earth metals.

This methodology involves two consecutive reactions that can be schematized as follows:

1. the titration reaction,

2. the indicator reaction [V],

The ingredients of the indicator reaction are added to the unknown solution (analyte inhibitor) in the

**Figure 4** Generic types of titration curve obtained by monitoring (A) a reactant and (B) a product of the indicator reaction (EP = end point). (Reproduced with permission from Pérez-Bendito D and Silva M (1988) *Kinetic Methods in Analytical Chemistry*. Chichester: Ellis Horwood.)

reaction vessel, and the catalyst is poured from a burette to start the titration reaction, which must meet the typical requisites for a conventional titration reaction (i.e., it should be fast and stoichiometric and develop to completion). The indicator reaction is only started by an excess of titrant (catalyst) after the endpoint and lends itself to instrumental monitoring via one of its reactants or products. Also, it is essential that the optimum conditions for development of the titration reaction (pH, solvent, ionic strength) should be the same as those for the indicator reaction.

Kinetic titration curves are constructed by plotting the relative analytical signal (absorbance, fluorescence, potential, or temperature) as a function of the volume of titrant added. If the two parameters are linearly related, then the titration curve will consist of two linear segments that can be extrapolated to intersect at the endpoint, as shown in **Figure 4**. Current instrumentation permits the use of automatic or semiautomatic devices capable of delivering the titrant and continuously monitoring the signal obtained. The time elapsed between the start of the titration and the endpoint is known as the pseudoinduction period and is proportional to the inhibitor concentration. These automated procedures are quite rapid and reproducible.

## Reaction Types

Homogeneous catalytic reactions can be classified into two broad categories: (1) ordinary catalytic reactions and (2) Landolt reactions.

### Ordinary Catalytic Reactions

This group of reactions includes redox, chemiluminescence, dissociation, and complex-formation reactions.

**Redox reactions** Redox reactions are by far the most common indicator reactions and typically

involve such oxidants as hydrogen peroxide, oxygen (usually atmospheric),  $\text{NO}_3^-$ ,  $\text{BrO}_3^-$ ,  $\text{ClO}_3^-$ ,  $\text{IO}_3^-$ ,  $\text{IO}_4^-$ , or  $\text{S}_2\text{O}_8^{2-}$  or inorganic reductants such as tin(II), arsenic(III),  $\text{I}^-$ , or  $\text{S}_2\text{O}_3^{2-}$ , or organic reductants such as ascorbic acid, hydrazine, hydroxylamine, amines, phenols, and azo dyes. Reactions between members of both groups with an electron transition in s- or p-orbitals are usually slow and therefore especially appropriate for indicator reactions. The catalysts determined are usually metal ions that possess vacant d-orbitals, have different oxidation states, and/or are capable of forming coordination compounds with one of the ingredients of the indicator reaction. Specifically, they are transition metals of one of the following types: (1) metal(IV) (zirconium, thorium); (2) metal(V) (niobium, tantalum, vanadium); (3) metal(VI) (molybdenum, tungsten); (4) metal(II) and (III) ( $\text{Fe}^{3+}$ ,  $\text{Mn}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$ , etc.); and (5) platinum metals and related metals (platinum, osmium, lead, ruthenium, rhodium, iridium, silver).

The most illustrative examples of redox indicator reactions are those involving the cerium(IV)/arsenic(III) system (Sandell–Kolthoff reaction), catalyzed by iodide ion; the iodine/sodium azide system, catalyzed by sulfur-containing compounds; the decomposition of hydrogen peroxide by copper, cobalt, manganese, and iron; the  $\text{H}_2\text{O}_2/\text{I}^-$ -system, catalyzed by iron, molybdenum, tungsten, zirconium, and hafnium; the hydrogen peroxide/hydroquinone system, catalyzed by copper; and the periodate/Malachite Green system, catalyzed by manganese. A number of automatic methods based on these systems have become the standards for determination of the corresponding catalysts in a wide variety of real samples.

The catalytic effect of iodide ion on the redox reaction between cerium(IV) and arsenic(III) was first shown and exploited for the determination of

this halide and its parent halogen at the nanogram per milliliter level by Sandell and Kolthoff. The reaction is carried out in a sulfuric acid medium, even though the catalytic activity of iodide is reportedly 20 times higher in nitric acid. The chloride ion inhibits the catalyzed reaction at concentrations of  $\sim 0.34 \text{ mol l}^{-1}$  or higher, whereas low concentrations of this halide increase the reaction rate and even expand the linear range of the calibration curve. The reaction can be monitored photometrically via cerium(IV), fluorimetrically through the cerium(III) produced, or electrochemically by using an amperometric or potentiometric sensor (including an iodide-selective electrode).

Not only iodide ion and iodine but also iodate and even periodate can be determined using this reaction by simply converting the analyte into the catalytically active species (i.e., iodide). The reduction is effected by arsenite ion itself on heating for 30 min. This treatment allows the resolution of iodate/iodide mixtures. The reaction can also be used for the determination of iodine-containing biological substances such as iodoproteins (thyroid hormones) by simply pretreating the samples in order to release iodine.

The reaction [VI] between sodium azide and iodine,

is catalyzed by substances containing sulfur in its  $-2$  oxidation state and has been used for the determination of anions such as sulfide, thiocyanate, and thiosulfate, as well as a variety of sulfur-containing organic compounds, with photometric or electrochemical monitoring.

Most often, these determinations rely on the oxidation of an organic compound, usually a dye, by hydrogen peroxide or an oxoanion such as bromate, iodate, or peroxodisulfate or even a chloramine derivative.

Both the cerium(IV)/arsenic(III) and the azide/iodine systems have also been used for the indirect determination of metal ions that interact with the catalyst, thus inhibiting the catalytic cycle, by use of a kinetic method or catalytic titration.

**Chemiluminescence reactions** Chemiluminescence reactions are usually redox reactions. The catalytic effect is reflected in the release of radiant energy. The best known of this type of reaction is the oxidation of luminol (5-amino-2,3-dihydrophthalazine-1,4-dione) by hydrogen peroxide, catalyzed by metal ions such as cobalt(II), copper(II), iron(II), nickel(II), chromium(III), and manganese(II) at pH 10–11. Detection limits of  $10^{-11}$  to  $10^{-8} \text{ mol l}^{-1}$  are readily achieved this way. Luminol is converted into a doubly charged anion that is subsequently oxidized to an excited singlet state that emits radiation on decomposing to

the aminophthalate ion. This reaction has been used for determination of the above-mentioned catalysts and hydrogen peroxide itself using copper(II) or cobalt(II) as the catalyst. Alternative oxidants include atmospheric oxygen and the peroxodisulfate ion – this latter is used for the determination of silver in the presence of amines. Though much less frequently used than luminol, lucigenin and lophine are also used as substrates in this type of reaction.

### Further Ordinary Catalytic Reactions

Kinetic catalytic methods based on catalytic decomposition, hydrolysis, ligand-exchange, or complex-formation reactions have a promising future as they allow the determination of nontransition metals such as alkaline earths (whether individually or in mixtures), in addition to ammonia and some other species.

### Landolt Reactions

Some catalyzed reactions involve an induction period, defined as the interval between addition of the last reactant (i.e., the start of the catalyzed reaction) and the appearance of a reaction product, during which the reaction appears not to develop. This phenomenon was first observed by Landolt in the reaction between iodate and sulfite ions in an acid medium, which releases iodine after an induction period. This is known as the Landolt effect and is chiefly exhibited by redox reactions involving halogens in various oxidation states. Thus, a slow reaction [VII] is coupled to a fast one [VIII] via the reaction product of the former:

Consequently,  $k_2 > k_1$  and P will only be detected after L (the Landolt reagent) has disappeared altogether in the second reaction. If reaction [VII] is accelerated by a catalyst, then the time elapsed until the product (P) appears will be a measure of the catalyst concentration, which is directly related to the induction period,  $t_1$ , by an empirical equation of the form  $[\text{C}]_0 = k_i/t_i$  or  $[\text{C}]_0 = k_i/t_i^2$ , depending on the particular system. Some slow reactions can be converted into Landolt reactions by using a retardant as the Landolt reagent.

This type of reaction is frequently used for analytical purposes on account of its simplicity and high sensitivity.

### Methods of Monitoring Reactions

Whenever a kinetic method is applied, the sample must be thoroughly mixed with the reagent(s) at a

constant temperature prior to transfer to the detection system. Mixing can be done manually (the usual situation with closed systems, which are applied to slow reactions such as the catalyzed reaction) or automatically. Automated mixing of the sample and reagents calls for special mechanical devices when fast reactions are involved as these require the use of open systems. However, open systems can be used in both catalytic titrations and kinetic catalytic determinations implemented in an automatic fashion for routine analyses.

For manual mixing it usually suffices to mix the reactants under continuous agitation in the reaction vessel, which may be a spectrophotometric or spectrofluorimetric cuvette or an electrode cell, or occasionally a thermometric cell. The time at which the last reactant is added (normally from a syringe) is taken as the start of the reaction ( $t=0$ ) and must therefore be accurately known. As a rule, the reactants and the cell compartment are thermostated prior to mixing. Alternatively, the sample and reagents can be mixed in a volumetric flask and made to the mark, and a portion of the diluted mixture be transferred to the detector cell.

The reactants can be incorporated into the measuring system automatically in order to increase the reproducibility of the above-mentioned closed or batch systems, equipped with photometric detectors, which are widely used in clinical laboratories.

Discrete stat and steady-state methods, whether automatic or semiautomatic, are frequently used for monitoring catalyzed reactions. Stat methods involve addition of a small amount of one of the reaction ingredients until a given value of the monitored parameter (pH, absorbance, luminescence, etc.) is reached. Any deviation from this state as a result of reaction development is immediately compensated for by the automatic addition of such an ingredient, the speed of signal restoration being proportional to the catalyst concentration. The procedure is referred to as pH-stat or absorptiostat method, according to whether the pH or absorbance is the continuously monitored parameter. Alternative techniques used to monitor the catalyzed reaction include biamprometry.

Steady-state methods entail keeping the speed of addition of a reagent constant throughout the process, thereby giving rise to a steady state in which the amount of reagent added is equal to that consumed in the reaction over a given interval. A plot of the steady-state concentration of the reagent as a function of the catalyst concentration can be used as a calibration graph for determining the catalyst.

Both stat and steady-state methods have been used for the kinetic determination of the iodide ion using its catalytic effect on the reaction between cerium(IV)

and arsenic(III) with photometric monitoring of the ceric ion added as the titrant at a variable (stat method) or constant (steady-state method) speed.

Although other commonly used open systems such as the stopped-flow methodology or the continuous-addition-of-reagent (CAR) technique are especially well suited to fast uncatalyzed reactions, they can also be applied to slow reactions.

## Detection Limits and Selectivity

Low limits of detection and high selectivity are important parameters in any analytical procedure. For a rough estimation of the minimum amount of catalyst that can be determined, eqn [4] may be transformed under an assumption of absence of the uncatalyzed reaction ( $k_1' = 0$ ) and  $[A] = [B] = 1 \text{ mol l}^{-1}$  to

$$\Delta[P] = k[C]_0 \Delta t \quad [6]$$

$$[C]_{0,\min} = (\Delta[P]/k\Delta t) \quad [7]$$

For photometric detection with

$$\Delta \text{absorbance} = \varepsilon_\lambda d \Delta[P] \quad [8]$$

it follows that

$$[C]_{0,\min} = (\Delta \text{absorbance} / \varepsilon_\lambda d k \Delta t) \quad [9]$$

Assuming a maximal molar absorbance,  $\varepsilon_\lambda$ , of  $10^5 \text{ (l mol}^{-1} \text{ cm}^{-1}\text{)}$ , a just measurable absorbance difference of 0.05, a reasonable optical length  $d$  of 5 cm, a practical time interval of 1 min, and a value of  $k' = 10^6 \text{ (cm}^{-1}\text{)}$ , the smallest determined catalyst concentration is calculated as  $10^{-13} \text{ mol l}^{-1}$ . The real limits of detection are some orders of magnitude higher than this theoretical value. The main reason is the influence of the background, especially by the extent of development of the uncatalyzed reaction. A comparison of the detection limits afforded by various catalytic methods in the determination of the most common ions reveals that the lowest achieved so far are in the  $10^{-9}$ – $10^{-7} \text{ mol l}^{-1}$  range and occasionally as low as  $10^{-10} \text{ mol l}^{-1}$  (kinetic determination of cobalt and vanadium, this latter in the presence of activators).

In contrast to the excellent detection power of the catalytic reaction, their selectivity is rather poor. Chemically similar species exhibit similar catalytic effects. This may be exemplified by the oxidation of different substrates by  $\text{H}_2\text{O}_2$  in acidic media (Table 2). In many cases a variation of the conditions in the indicator reaction will help to increase selectivity. Change of pH, reagent concentrations or temperature, addition of suitable complexing agents for activation,

inhibition or masking, and selection of appropriate detection techniques may greatly increase the selectivity of such reactions. If these procedures will not help, a preliminary separation step is necessary. Besides chromatographic methods, solvent extraction has proved to be effective, especially when the indicator reaction could be performed in the organic extract without the need for a stripping process (extraction-catalytic determination (Table 3).

## Analytes Determined

Determinations of major analytes using the catalytic reaction typically involve kinetic assays for metal ions as catalysts since for anions the number of possible indicator reactions is limited.

Primary catalytic effects are seldom exploited for the catalytic determination of organic compounds unless they can act as carriers for inorganic catalysts, as is the case with the determination of organic iodine-containing compounds using the Sandell-Kolthoff reaction. The most salient methods of this type for determination of metal ions, inorganic anions, and organic compounds are commented on in the following sections.

### Determination of Metal Ions

Table 4 shows some selected indicator reactions for the kinetic determination of transition metal ions (e.g., copper, cobalt, manganese, iron, vanadium) as

catalysts for various indicator reactions alongside their working conditions and analytical figures of merit. Note that photometric detection and the use of activators to enhance the sensitivity, in addition to the oxidation of organic compounds, are the most common choices in this context. Some ions (e.g., zinc, indium, gallium, selenium, tellurium, mercury) can also be determined kinetically using their activating effects on metal-catalyzed reactions or their inhibitory effects (mercury, gold, silver, copper, nickel, tin, magnesium) on nonmetal-catalyzed reactions (chiefly those involving the cerium(IV)/arsenic(III) system) or metal-catalyzed reactions. Depending on the particular metal and reaction, concentrations between a few nanograms per milliliter and a few micrograms per milliliter can be determined this way.

### Determination of Anions

Most kinetic determinations of anions involve the iodide ion, which exhibits a strong catalytic effect on the reaction between cerium(IV) and arsenic(III) and a few others as a result of the redox properties of the  $I_2/I^-$  couple. Other anions that can be determined using their intrinsic catalytic effect include sulfur-containing species such as sulfite, sulfide, and thiosulfate, which are quantified by means of the iodine/sodium azide system, and phosphates, which are measured through their effect on the formation of molybdenum blue. Table 5 gives illustrative examples of determinations for these anions and a few others.

Several anions such as cyanide, fluoride, and sulfide can also be determined kinetically at concentrations between 0.1 and  $4 \mu\text{g ml}^{-1}$  through their inhibitory effects on various metal-catalyzed reactions or, at somewhat higher concentrations, by direct catalytic titration.

### Determination of Organic Compounds

Most organic compounds of analytical interest in such areas as environmental or clinical chemistry

**Table 2** Indicator reactions with  $H_2O_2$  as oxidant

Indicator reaction	Catalyst
$H_2O_2 + I^-$	Ti, Zr, Hf, Th, V, Nb, Ta, Cr, Mo, W, Fe(III), $Cr_2O_7^{2-}$ , $PO_4^{3-}$
$H_2O_2 + S_2O_3^{2-}$	Ti, Zr, Hf, V, Nb, Ta, Mo, W
$H_2O_2 + PhOH$ , $PhNH_2$	Cr, Mn, Fe, Co, Ru, Os, Cu
$H_2O_2 + H_2(NHCS)_2$	Mo, W
$H_2O_2 + \text{organic dyes}$	Fe, Cu, Cr, Mn, Co, Ni

**Table 3** Extraction catalytic determinations

Analyte	Separation system	Indicator reaction	Observations
Ag	Phen/Bromopyrogallol Red (BPR)/nitrobenzene	$BPR + S_2O_8^{2-} + \text{phen}$ in a mixture of dioxane, nitrobenzene, and water	Extraction from EDTA-complexed solution
Mo	8-Hydroxyquinoline/ $CHCl_3$	1-Naphthylamine + $BrO_3^-$ in water/alcohol/ $CHCl_3$	Used for determination in seawater
Fe	Methyl isobutyl ketone(MIBK) + LiCl	<i>p</i> -Phenetidine + $H_2O_2$ (phen as activator)	Determination of iron traces in reagent grade salts of Co, Cu, Ni, Mg
$Cr_2O_7^{2-}$	MIBK + HCl	<i>o</i> -Dianisidine + $H_2O_2$	Determination in Cr(III) salts
Cu	$Cu(py)_2(Hsal)_2$ in $CHCl_3$	Sulfanilic acid + $H_2O_2$ (py as activator)	Determination in liver biopsy samples

phen, 1,10-phenanthroline; sal, salicylate; py, pyridine

Rhodamine B + KIO <sub>4</sub> <sup>b</sup>	0.05–6.0	1,10-Phenanthroline as activator; pH 2.4
Tiron + H <sub>2</sub> O <sub>2</sub> <sup>a</sup>	5–40	Flow-injection technique (40 samples per hour)
Oxidative coupling of 3-methyl-2-benzothiazolinone hydrazone with <i>N,N</i> -dimethylaniline by H <sub>2</sub> O <sub>2</sub> <sup>a</sup>	2–30	1,10-Phenanthroline and citrate used as activators flow-injection technique (10 samples per hour)
<i>Iron</i>		
Decomposition of H <sub>2</sub> O <sub>2</sub> <sup>a</sup>	50	1,10-Phenanthroline as activator
	1–13	Catalyzed by Fe(III)-triethylenetetramine
I <sup>-</sup> + H <sub>2</sub> O <sub>2</sub> <sup>c</sup>	5–160 µmol l <sup>-1</sup>	Iodide-selective electrode
Pyridoxal 2-pyridylhydrazone + H <sub>2</sub> O <sub>2</sub> <sup>b</sup>	5–60	
<i>N</i> -phenyl- <i>p</i> -phenylenediamine + <i>N,N</i> -dimethylaniline + H <sub>2</sub> O <sub>2</sub> <sup>a</sup>	0–6	Acetate as activator
Sulfanilic acid + KIO <sub>4</sub>	11–56 <sup>a</sup>	1,10-Phenanthroline as activator
	50–220 <sup>d</sup>	Fixed-time method ( <i>t</i> = 10 min)
	5–160 µmol l <sup>-1</sup>	In a micellar medium (cetylpyridinium chloride) with 1,10-phenanthroline as activator
Methylene Blue + H <sub>2</sub> O <sub>2</sub> <sup>a</sup>	0.04–12	1,10-Phenanthroline as activator
Rhodamine B + H <sub>2</sub> O <sub>2</sub> <sup>a</sup>	0.04–150	Accelerated by potassium thiocyanate; fixed-time method ( <i>t</i> = 12 min)
Thymol Blue + H <sub>2</sub> O <sub>2</sub> <sup>a</sup>	0–3.2	2,2'-Bipyridyl as activator

Monitoring: <sup>a</sup>photometric, <sup>b</sup>fluorimetric, <sup>c</sup>potentiometric, <sup>d</sup>thermometric, <sup>e</sup>amperometric, <sup>f</sup>biamperostat, <sup>g</sup>absorptiostat, <sup>h</sup>potentiostat.

are determined on the basis of uncatalyzed reactions as they scarcely exhibit primary catalytic effects. Some organic substances such as thyroid hormones, cysteine, vitamin B<sub>1</sub>, and thiurea derivatives

have been determined because they contain atoms that can act as catalysts (e.g., iodine, sulfur) in the above-mentioned indicator reactions. Thus, vitamin B<sub>12</sub> is determined through its cobalt atom,

which catalyzes various indicator reactions involving oxidation of organic dyes by hydrogen peroxide.

Aminopolycarboxylic acids (ethylenediaminetetraacetic acid (EDTA), 1,2-diaminocyclohexanetetraacetic acid, bis-(aminoethyl)glycoether-*N,N,N',N'*-tetraacetic acid, diethylenetriaminepentaacetic acid and nitroacetic acid) can be quantified through their inhibitory effects on metal-catalyzed reactions, whether by kinetic methods (at concentrations between  $10^{-6}$  and  $10^{-7}$   $\text{mol l}^{-1}$ ) or by direct catalytic titration

(at the microgram per milliliter level). Also, NTA has been determined as an activator for some manganese(II)-catalyzed reactions.

Other organic species are determined kinetically at the microgram per milliliter level through their activating (ascorbic acid, citric acid, bipyridyl, 1,10-phenanthroline, pyridine) or inhibitory (8-hydroxyquinoline, dimethylglyoxime, chromotropic acid, tetracyclines, amino acids, nitrogen-containing drugs) effects on various metal-catalyzed reactions at the microgram per milliliter level.

ability to resolve mixtures of closely related species using differential reaction rate methods. These advantageous features allow the determination of traces of species in environmental wastes and foods with no preconcentration, as well as in minute amounts of biological, forensic, or geological samples. In addition, the joint use of chromatographic techniques and kinetic catalytic methods is the most

effective approach to solving the problems arising from the low selectivity of some catalytic and chemiluminescence methods.

Although the applications of kinetic methods span many areas (industrial products, geochemistry and agricultural chemistry, food analysis, analytical-grade reagents), many of them are concerned with environmental, clinical, and pharmaceutical chemistry.

**Figure 5** Significance of kinetic methods in their different areas of application: catalytic reactions (clear areas), chemiluminescent reactions (dotted areas), and uncatalyzed reactions (shaded areas). ### Environmental Chemistry

The features of environmental samples make them especially suitable for automated kinetic analyses. The determination of metal ions in environmental samples is of great ecological significance as these species cannot be degraded biologically or chemically. Kinetic methods are useful tools for determining heavy metals in environmental water and air, where toxic species occur at low concentration levels. **Table 6** collates some relevant applications, among which those concerned with water analyses are prominent.

### Clinical and Pharmaceutical Chemistry

Although kinetic methods of analysis are of special significance to clinical and pharmaceutical analysis in relation to enzymatic methods, they are equally applicable to nonenzymatic processes. **Table 7** shows the most salient contributions reported in this respect over the past few years. Most of the clinical determinations shown have been performed on blood and/or urine samples and have involved inorganic or organic ions in similar proportions. On the other hand, pharmaceutical determinations have chiefly been concerned with organic substances. The Sandell–Kolthoff reaction has by far been the most commonly employed for the analysis of biological samples, so much

so that some clinical handbooks have recommended it for the determination of thyroid hormones such as tri- or tetraiodothyronine ( $T_3$  or  $T_4$ ). **Figure 5** summarizes developments in kinetic methods for the analysis of real samples reported over the past 10 years in various areas of interest. Uncatalyzed reactions are included for comparison. As can be seen, catalyzed reactions are the most commonly used, followed by chemiluminescent and uncatalyzed reactions.

### Introduction

Concepts of ‘micro-total analysis systems’ or analytical ‘labs-on-chips’ stemmed from the experience that chemical analysis in liquids can be performed in capillary networks fabricated on planar substrates. The first systems utilized the technological developments of the microelectronic industries, i.e., silicon wafers were used as substrate materials, and capillaries were formed by etching. Flow of liquid was controlled by miniaturized pumps and valves. Further integration of functionalities was achieved by the replacement of hydrodynamic liquid transport by the electroosmotic control of liquid flow, as mechanical parts such as pumps and valves could be replaced by electrodes, which were integrated in the chips. Moreover, the utilization of electric fields for liquid transport led to the separation of mixtures of compounds due to different electrophoretic mobilities, and thus opened the possibilities for the performance of different analytical assays within those chips. However, as the separation of compounds required high electric field strengths, alternative substrate materials had to be investigated with a higher electric resistance than silicon. Thus, nowadays glass is frequently used as substrate material due to its favorable electric and optical properties and ease of structuring by wet etching. Nowadays, polymers are also investigated for their applicability as chip materials, for example, poly(methyl methacrylate) (PMMA), polycarbonate (PC), and poly(dimethylsiloxane) (PDMS).

As miniaturization proved to be advantageous with respect to analysis time and volumes of sample and reagents required, research with these technologies spread and at the end of the 1990s the first instrument was introduced to the market for capillary electrophoretic separations of double-stranded DNA fragments by Caliper Technologies Corp./Agilent Technologies.

The establishment of an analytical assay in a microsystem is the transfer of the assay in a capillary flow-through system, leading to the necessity to consider some particular aspects:

1. Due to the reduction of geometrical dimensions the surface-to-volume ratio is larger than in conventional systems and surface properties are more important. Thus, the chemical nature of the surface, surface pretreatment procedures, and the adsorption of components on the surface are of utmost importance.
2. Due to the small dimensions of capillaries the flow resistance for pressurized flow of liquid increases. Thus, alternative methods for liquid transport are used and at present the most important principle is electroosmosis requiring the integration of electrodes, usually platinum electrodes, and the application of electric fields. Additionally, centrifugal forces are used for propelling liquid through capillary systems. In some systems these principles are combined with pressurized liquid transport.
3. The reduction of dimensions also reduces volumes that are accessible for the detector. Thus, detection principles that are related to the volume of the detector cell, as absorbance measurements, are not ideally suited for coupling to microsystems, whereas surface sensitive principles, such as electrochemical methods or optical methods utilizing the evanescent field of a waveguide, or methods that can be focused on a small amount of liquid, such as fluorescence, are better suited. That is why fluorescence detectors are most often combined with microsystems, with an increasing number of reports appearing on the integration of electrochemical detectors.

### Principles

Labs-on-chips are planar capillary systems in which the capillaries are typically 10–50  $\mu\text{m}$  deep and 10–400  $\mu\text{m}$  wide. The channels are several centimeters long to allow mixing of components, the performance of (bio)chemical reactions, or the separation of compounds. A typical layout is shown

schematically in **Figure 1**, with a cross of capillaries being the simplest version, such as the part of the network formed by reservoirs 2, 3, 6, and 7. Reservoirs serve as interfaces to all required solutions. The design of the intersection of capillaries influences the volume of liquid introduced into reaction or separation channels. Often a double-T layout (insert in **Figure 1**) is used to increase volumes.

### Substrate Materials

Early reports were based on devices produced by etching and bonding of silicon, as these technologies were well established from the fabrication of micro-electronic devices. However, electroosmotic transport of liquid requires the application of electric fields (see below) and, thus, suitable substrates have to have a high electric resistance. Moreover, the combination with optical detectors is facilitated by glass as substrate material. Thus, etching processes and bonding procedures were also established for glass substrates.

Polymers are discussed as less-expensive alternatives to glass, in particular with respect to mass production of structures. Injection molding, hot embossing, wire imprinting, and laser ablation are among the technologies that were established to

produce required capillary structures in PC, polystyrene, PMMA, poly(ethylene terephthalate), poly(vinyl chloride), or cellulose acetate. Major problems are related to bonding a cover plate to the structured substrate to close the capillaries tightly, without deforming capillary dimensions. Solutions range from adhesive tape lamination to gluing, and the application of heat or pressure.

Besides these rigid polymers, PDMS is widely used in recent studies, because structures are easily fabricated without the need for specialized equipment and PDMS shows good adhesion to a number of materials, e.g., glass, facilitating the tight closure of channels. Compared to glass, polymers are often more hydrophobic, which hinders an easy filling of structures with aqueous solutions and leads to an increased adsorption of hydrophobic compounds on capillary surfaces. Thus, fabrication conditions have to be chosen resulting in hydrophilic surfaces, or surfaces are treated after processing, such as by modification with charged polymers or by treatment with plasma or with  $\text{SO}_3$  vapor from fuming sulfuric acid (**Table 1**).

### Electrokinetic Control of Liquid Flow

**Principle** If an electric field is applied parallel to the long axis of a capillary, two migration mechanisms

PDMS, poly(dimethylsiloxane); PET, poly(ethylene terephthalate); PC, polycarbonate; PMMA, poly(methyl methacrylate); PVC, poly(vinyl chloride); LTCC, low-temperature cofirable ceramics; MES, 2-morpholinoethanesulfonic acid; SDS, sodium dodecyl sulfate.

for compounds are induced: electrically charged molecules move within the electric field according to their charge, i.e., positively charged molecules migrate to the cathode, negatively charged molecules to the anode. This mobility is called the electrophoretic mobility of compounds and is dependent on the electric field strength, the viscosity of the solution, and the charge and size of the molecule. It is the reason for the separation of compounds on the basis of the charge-to-size (mass) ratio in electrophoresis. This mobility is superimposed on the electroosmotic mobility of the buffer. Within a capillary with a charged surface an electric double layer is formed by the ions present in solution, with oppositely charged ions from the solution being most close to the capillary surface (Figure 2).

**Figure 2** Schematic representation of the principles of capillary electrophoresis and electroosmotic flow.

This results in the so-called  $\zeta$  potential, which is dependent on the charge density on the capillary surface and the type and concentration of ions present in the solution. Application of an electric field perpendicular to this double layer, i.e., parallel to the surface or the long axis of the capillary, forces the ions next to the capillary surface to migrate according to their charge. Thus, the whole layer of ions neighboring the capillary surface moves in one direction, together with the corresponding shell of water molecules. By viscous forces this movement of the surface layer is transferred to adjacent solution layers so that the whole liquid within the capillary is moved toward the electrode charged with the same polarity as the capillary surface (Figure 2). This electroosmotic flow (EOF) rate  $\nu_{\text{osm}}$  is dependent not only on the electric field strength  $E$ , but also on the  $\zeta$  potential of the capillary and thus on the capillary material and treatment of the capillary surface. The Helmholtz–Smoluchowski equation relates these parameters according to

$$\nu_{\text{osm}} = -(\epsilon\epsilon_0\zeta/\eta)E = \mu_{\text{osm}} \times E = \mu_{\text{osm}} \times V/L$$

where  $\mu_{\text{osm}}$  is the electroosmotic mobility,  $L$  the length of the capillary,  $V$  the applied voltage,  $\epsilon$  and  $\eta$  the dielectric constant (78 for water) and viscosity of the medium, respectively, and  $\epsilon_0$  the permittivity of the vacuum ( $8.85 \times 10^{-12} \text{ C}^2 \text{ N}^{-1} \text{ m}^{-2}$ ).

$\nu_{\text{osm}}$  is the rate of liquid movement along the length of the capillary and is determined via the time required to transport solutions from the entrance of the capillary to the waste reservoir. In most materials the capillary surface is negatively charged so that the EOF is directed from the anode to the cathode.

**Influence of surface properties** As mentioned above, polymeric surfaces are usually more hydrophobic than glass surfaces due to the reduced density of polar or even ionized groups. Thus, the EOF is lower in most polymeric capillaries. The addition of ionic detergents to the running buffer not only allows a smooth filling of these capillaries with aqueous solutions, but also leads to the adsorption of detergents on the surface influencing the charge density on the surface, and thus the electroosmotic mobility (Table 1). Depending on the charge of the detergent, the EOF can even be reversed, which is marked by a negative sign in Table 1. Moreover, these modifications lead to a stabilization of the EOF in polymeric chips and reduce the unwanted adsorption of hydrophobic analytes on the capillary surface, thus improving the analytical properties (Table 2).

As the EOF is based on the presence of ionic groups on the surface of the capillary it is dependent on the pH of the solution, usually increasing with pH. Silanol groups on the surfaces of glass capillaries are minimally ionized at low pH, resulting in a low EOF; increasing the pH increases the density of negative charge on the capillary surface and thus the EOF. Depending on the  $\text{pK}_a$  of functional groups present on the capillary surface, the pH dependence is more or less pronounced in the pH range investigated and more or less shifted compared to glass capillaries.

### Injection of Samples

The resolution obtained in microfabricated separation systems and signals resulting from (bio)chemical transformations are limited not only by experimental conditions, such as composition of

**Table 2** Examples for the influence of additives to the running buffer on the analytical performance of microfluidic chips; abbreviations see Table 1

Additive	Chip material	Example of an effect of the additive
Hydroxypropylmethylcellulose	PMMA	Avoids adsorption of fluorescently labeled oligosaccharides to capillary surfaces
Methylcellulose		
Hydroxyethylcellulose		
Hydroxypropylmethylcellulose + mannitol, glucose, or glycerol		Improves separation of PCR products by low-viscosity sieving matrix
SDS	Glass	Allows micellar electrokinetic chromatography of peptides or proteins
Hydroxyethylcellulose		Allows seizing/separation of PCR products
Poly(vinyl pyrrolidone)	Pyrex glass	Improves separation efficiency of labeled amino acids and small peptides
Polybrene, dextran sulfate	PDMS	Avoids adsorption of neutral compounds to the capillary surface
MES	PDMS	Reduces the electroosmotic mobility and the adsorption of analytes, such as glucose or amino acids
Poly(vinyl alcohol)	Borofloat glass	Improves separation of labeled amines, allows separation of chiral amines

the running background electrolyte or electric fields applied during separation or reaction, but also by the sample volume, in particular by the chip layout. The volume of the injected sample is mainly determined by the channel dimensions and the offset between channels 3 and 6 (Figure 1), which typically ranges from 0 (no offset, simple cross) to  $\sim 250\ \mu\text{m}$ .

Additionally, the amount of injected sample can be influenced by the electric field strengths applied to sample and buffer reservoirs during injection. In the simplest injection mode first an electric field ( $> 100\ \text{V cm}^{-1}$ ) is applied between one of the upper reservoirs and reservoir 3 leading to filling of the capillary with sample, in particular of the intersection between the buffer capillary (6 and 7) and the capillary introducing the sample (grounded in reservoir 3). In the analysis step the electric field is switched to reservoirs 6 and 7, so that the sample is moved to the detector placed near buffer waste reservoir 7. For most substrate materials (negative surface charge) and analytes, the waste reservoirs (3 and 7) are electrically grounded and a positive voltage is applied to the sample or buffer reservoir, i.e., during analysis, injection respectively, the waste reservoirs are connected to the cathode, the sample and buffer reservoirs to the anode of the high-voltage supply.

With fluorescently labeled compounds and corresponding camera systems it was shown that in the intersection of the two capillaries, broadening of the sample plug during the injection step occurred due to diffusion of sample constituents into the long channel. During the analysis step sample still migrated into the long channel from the sample channels again by diffusion, but also by viscous effects. Both effects lead to less well defined, broadened sample plugs with reduced separation efficiencies of sample constituents. Thus, alternative injection regimes to shapen the sample plug by more complex control of electric fields were introduced. In the 'floating injection mode' the long channel is still floating during injection, whereas during analysis an electric field is generated in the sample channel so that buffer moves from the buffer reservoir 6 not only to the buffer waste reservoir 7, but also to sample reservoirs. This avoids leakage of sample into the long analysis channel during analysis (pushback effect). Diffusion of sample into the long channel during injection is suppressed by the 'pinched injection mode'. This requires application of an electric field to the long channel during injection so that not only a sample but also a buffer flow to the sample waste reservoir 3 is generated. This not only avoids the leakage of sample into the long channel during injection but

also reduces the amount of sample present in the intersection. Voltages to be applied to the different electrodes and the chronological sequence of the different steps have to be adapted to the respective chip layout and sample matrix.

## Detectors

Conventional chromatographic or capillary electrophoretic devices are based on analyte detection by absorbance, for example, of ultraviolet (UV) light. However, in chip-based systems absorbance measurements are the exception as detection cells have to be developed leading to an extension of the path-length of the transmitted light.

Thus, the detectors most often used in microchips are fluorescence detectors, in which laser light is focused in the channel to excite corresponding fluorescent dyes and the emitted light is collected by microscope objectives and detected by photomultiplier tubes. Though these detectors allow the detection of low numbers of molecules, the general application is hindered by the need for fluorescent compounds. To circumvent this problem, the principle of indirect fluorescence is used, in which a fluorophore is added to the background electrolyte and replaced by nonfluorescent analytes during analysis. Thus, these compounds are detected via the reduction of the high background signal.

Due to the ease of fabrication of miniaturized electrodes and the compatibility of corresponding technologies with fabrication technologies for microfluidic chips the combination of electrochemical detectors with microchips gains in interest. The major problem is the decoupling of the electrochemical detection from the electric field used for liquid control. This is achieved by positioning the detector electrodes close to the exit of the capillary so that the electric field generated by the high-voltage supply is dropped almost completely. Alternatively, electrodes are placed within the capillary requiring additional decouplers, which may be a small fracture in the capillary, or a palladium or platinum film placed in front of the working electrodes. However, though electrochemical detectors can be integrated in the chip already during fabrication, they are also connected to the capillary system via suitable chip holders allowing the applicability of electrode materials optimal for the selective and sensitive detection of the analytes and not limited by the fabrication technology.

There are reports on additional detectors connected to microfluidic devices the importance of which will increase with the robustness of interfaces. In particular with respect to applications in the life

sciences microchips were connected to mass spectrometry, and recently a microthermocouple was described allowing the determination of heat generated by a chemical reaction.

### World-to-Chip Interface

Though a number of steps of the analytical procedure can be performed automatically within the chip, samples and reagents have to be introduced into the chip; thus, the interface between the 'macroworld' and the microsystem has to be designed. The first chips comprised reservoirs at the ends of the capillaries, i.e., in the cover plate used for closing the capillaries, holes were drilled allowing access to the ends of the capillaries so that electrodes needed for electroosmotic fluid flow control could be placed from the top into these holes. The volumes were given by the diameter of the holes (typically 1–3 mm) and by the thickness of the respective cover plate (<1 mm) and were in the order of magnitude of microliters. Thus, liquid movement for several minutes may reduce the level in these reservoirs significantly, which causes pressure differences and thus additional hydrostatic effects. To increase the volumes of reservoirs and simplify placement of electrodes in first reports plastic pipette tips or tubings were glued to the substrates. However, this procedure is feasible only for single reservoirs and single chips and is replaced nowadays by chip holders with integrated reservoirs. Sample throughput is increased by parallelization of analysis channels and the application of multichannel pipettes. Those chips are used for

quality control, for example, of protein – or RNA – preparations, or in food or water analysis (Table 3).

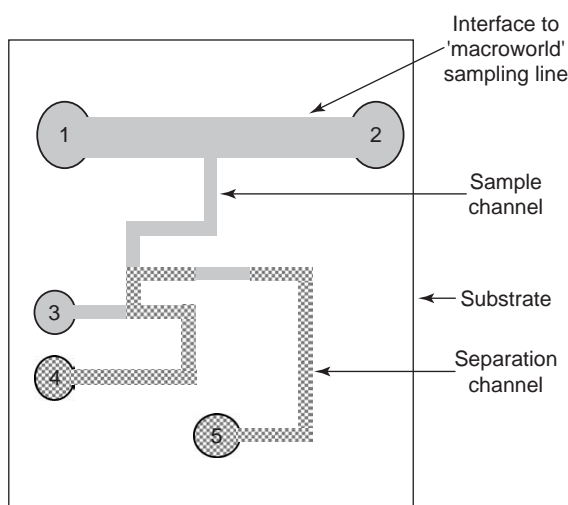

Labs-on-chips that are developed for drug screening need access to microtiter plates, in which the compounds of interest are stored. These chips contain sipper capillaries through which samples are introduced into the microchannels by vacuum. Continuous analysis of samples is possible if the chip contains a sample channel of larger dimensions (approximately in the millimeter scale), through which sample solutions are pumped hydrodynamically and which is connected to the separation or reaction channel. The principle is illustrated in Figure 3. To increase the impedance against pressure-induced flows the separation channel may be filled with a gel.

As illustrated by the examples given in Table 3, the application of labs-on-chips to real samples is still limited. This is partly due to the fact that the analytical assay is only the final step of the whole procedure, which includes sample pretreatment protocols such as filtration, analyte cleanup, or analyte preconcentration. However, also the integration of corresponding microfabricated elements is described. Filtration was achieved by porous membranes or arrays of thin channels preventing particulates to enter the analytical device. Analyte preconcentration in combination with removal of other sample constituents is achieved by solid-phase extraction modules, which are either capillaries or beads coated with a suitable adsorbent, such as a C18 phase originating from coating with octadecyltrimethoxysilane, from which the analyte is

eluted in a subsequent step. Another widespread method for analyte enrichment involves control of the electrophoretic velocities of analytes and includes field-amplified sample stacking (FASS) as the simplest method. In FASS, the sample is prepared in a low-conductivity buffer, whereas the running buffer is of higher conductivity. Thus, when voltage is applied the electric field strength in the sample zone is higher than in the running buffer zone, leading to a higher mobility of charged analytes in the sample zone. Reaching the interface to the running buffer analyte ions decelerate abruptly and stack in a narrow discrete sample band resulting in significant signal gains of up to three orders of magnitude.

Integration of the whole analytical procedure ranging from sample pretreatment procedures to the analytical signals leads to true analytical labs-on-chips.

## Assays

Microchips offer various possibilities for the performance of analytical assays: they comprise a capillary system, to which electric fields can be applied, which is the principle of capillary electrophoresis (CE). Thus, capillary electrophoretic separation assays can be transferred to microchips leading to the accelerated separation of compounds, in particular of carbohydrates, amino acids, peptides, proteins, and nucleic acids. In Table 3, some representative assays are summarized with special emphasis on the practical applications.

The broad range of possible analytes and sample matrices stems from the possibilities to connect the chip to different detectors, though fluorescence detectors are the predominant, and to use different separation modes (CE, isotachopheresis, reversed-phase electrochromatography) as different buffer additives, sieving matrices, capillary wall coatings, or capillary packings can be used. As mentioned above and summarized in Table 2, detergents and polymers added to the running background electrolyte interact with the capillary wall and prevent the adsorption of proteins to glass surfaces or of neutral analytes to polymeric surfaces. However, detergents form micelles, if they are used in concentrations above the critical micelle concentration, leading to the entrapment of analytes and their separation based on micellar electrokinetic chromatography and polymers, such as hydroxyethylcellulose, serve as sieving matrix allowing the separation of nucleic acids. In addition to these dynamic coating procedures, capillaries are permanently coated by silanization or filled with gels or beads. The interaction of compounds with these permanent coatings or fillings may lead to a strong adsorption of analytes within the capillary requiring the subsequent elution by appropriate solutions, such as acetonitrile gradients. This phenomenon leads, on the one hand, to the implementation of chromatographic methods in chips and, on the other hand, to the integration of solid-phase extraction procedures for analyte cleanup and preconcentration.

However, labs-on-chips are used not only in separation-based assays but also as flow-through devices allowing the performance of (bio)chemical reactions, such as enzymatic transformations or antigen–antibody interactions. Usually products of the reaction are quantitatively determined allowing the estimation of enzyme substrates, enzyme inhibitors, the respective kinetic and thermodynamic constants, or of antigens/antibodies. The assays can be performed in a homogeneous format or with immobilized biomolecules. The immobilization substrate can be the capillary surface leading to open-tubular enzyme or antibody reactors. The surface area, to which the immobilized proteins are restricted, is defined by channels through which solutions are pumped for a permanent coating of the surface with compounds introducing functional groups for covalent or adsorptive protein coupling. As an alternative approach, proteins can be immobilized on microbeads, which are entrapped within reaction chambers defined by weirs, which leave an open space too small to allow the beads to leave the system but allow solutions to pass. Due to the versatility of the layout of microchip capillary systems,

**Table 4** Examples for biochemical analytical assays performed in microfluidic chips

<i>Application</i>	<i>Biological element</i>	<i>Format</i>	<i>Detection</i>
Enzyme inhibitor screening	$\beta$ -Galactosidase $\beta$ -Glucuronidase	Mixing substrate, protein, and inhibitor	Fluorescence
Enzyme inhibitor screening	Acetylcholinesterase	Mixing substrate, protein, inhibitor; detection of product after further derivatization	Fluorescence
Enzyme inhibitor screening	Protein kinase A	Mixing fluorescently labeled peptide, protein, inhibitor, electrophoretic separation of phosphorylated product and nonphosphorylated substrate	Fluorescence
Enzyme inhibitor screening	$\beta$ -Galactosidase	Mixing inhibitor and substrate, enzyme immobilized on membrane	Fluorescence
Enzyme activity determination	Extracellular signal-regulated protein kinase	Mixing fluorescently labeled peptide, protein, inhibitor, electrophoretic separation of phosphorylated product and nonphosphorylated substrate	Fluorescence
Glucose determination	Glucose oxidase	Injection of sample in enzyme containing running electrolyte, electrophoretic separation from interferents	Amperometry (Au electrode)
Glucose determination	Glucose oxidase + horseradish peroxidase	Both enzymes co-immobilized via biotin–streptavidin on capillary wall	Fluorescence (Resorufin)
Sucrose	Invertase, glucose oxidase, soybean peroxidase	Enzymes covalently co-immobilized on capillary wall	Fluorescence (poly ( <i>p</i> -cresol))
Proteins	Trypsin	A reactor bed for immobilized trypsin in combination with a separation channel	Electrospray ionization mass spectroscopy
Trinitrotoluene	Specific antibodies	Affinity capillary electrophoresis by mixing antibody, analyte, and a labeled analyte analog, electrophoretic separation of antibody complex from noncomplexed tracer	Fluorescence
Mouse antibodies	Antimouse antibodies	Mixing of analyte with antibodies labeled with horseradish peroxidase, electrophoretic separation of the noncomplexed antibody, detection of label via mixing with enzyme substrates	Chemiluminescence
Interferon- $\gamma$	Specific antibodies	Sandwich immunoassay with capture antibody immobilized on beads, colloidal gold as tracer	Thermal lens microscope
Rabbit antibodies	Protein A	Competitive immunoassay with protein A immobilized on the walls of the capillary and Cy5-labeled antibodies as tracer	Fluorescence
Gene analysis	DNA polymerase	Amplification of gene sequences by PCR and electrophoretic separation of PCR products	Fluorescence
Drug screening	T lymphocytes (whole cells)	Mixing samples with cells, and additionally with membrane potential fluorescent dyes; detects ion channel activity	Fluorescence

electrophoretic separations can be combined with biochemical reactions (a possible layout is shown in **Figure 1**). This feature is utilized if signals from the educt and product of the reaction, or from sample constituents and the reaction product cannot be distinguished by the detector. Examples are the phosphorylation of fluorescently labeled peptides by kinase reactions, which does not change the fluorescence of the peptide, but its electrophoretic mobility

so that the phosphorylated form can be separated from the nonphosphorylated one, or the separation of polymerase chain reaction (PCR) products when the PCR is performed also on the chip. Some examples of biochemical assays performed in microchips are collected in **Table 4**.

## Introduction

In analytical atomic spectrometry, lasers are employed either as sources of tunable radiation of precise wavelength or as sources of collimated, intense radiation. Laser sources that emit tunable radiation of low divergence in a well-defined spectral wavelength interval are the most powerful new techniques introduced in optical spectroscopy. They enable experiments to be carried out in basic atomic and molecular spectroscopies that were not possible using classical methods of optical spectroscopy. Such experiments include the evaluation of fundamental spectroscopic parameters, more precise determinations of spectral wavelengths of optical transitions, direct measurements on atomic and molecular beams, and Doppler-free high-resolution spectroscopy. Moreover, the new laser techniques improve the analytical capability of the classical spectrochemical methods, yielding much higher selectivity, larger dynamic range, and lower limits of detection.

In atomic laser spectroscopy, the laser radiation, which is tuned to a strong dipole transition of the atoms under investigation, penetrates the volume of species evaporated from the sample. The presence of analyte atoms can be measured by means of the specific interaction between atoms and laser photons, such as by absorption techniques (laser atomic absorption spectrometry, LAAS), by fluorescence detection (laser-induced fluorescence spectroscopy, LIFS), or by means of ionization products (electrons or ions) of the selectively excited analyte atoms after an appropriate ionization process (**Figures 1A and 1B**). Ionization can be achieved in different ways: (1) by interaction with an additional photon of the exciting laser or of a second laser (resonance ionization spectroscopy, RIS, or resonance ionization mass spectrometry, RIMS, respectively, if combined with a mass detection system); (2) by an electric field applied to the atomization volume (field-ionization laser spectroscopy, FILS); or (3) by collisional ionization by surrounding atoms (laser-enhanced ionization spectroscopy, LEIS).

Since its commercial availability, the laser has been used extensively as a source of powerful radiation. If the laser radiation is focused on to a solid sample, a small volume of the sample material can easily be

## Introduction

In analytical atomic spectrometry, lasers are employed either as sources of tunable radiation of precise wavelength or as sources of collimated, intense radiation. Laser sources that emit tunable radiation of low divergence in a well-defined spectral wavelength interval are the most powerful new techniques introduced in optical spectroscopy. They enable experiments to be carried out in basic atomic and molecular spectroscopies that were not possible using classical methods of optical spectroscopy. Such experiments include the evaluation of fundamental spectroscopic parameters, more precise determinations of spectral wavelengths of optical transitions, direct measurements on atomic and molecular beams, and Doppler-free high-resolution spectroscopy. Moreover, the new laser techniques improve the analytical capability of the classical spectrochemical methods, yielding much higher selectivity, larger dynamic range, and lower limits of detection.

In atomic laser spectroscopy, the laser radiation, which is tuned to a strong dipole transition of the atoms under investigation, penetrates the volume of species evaporated from the sample. The presence of analyte atoms can be measured by means of the specific interaction between atoms and laser photons, such as by absorption techniques (laser atomic absorption spectrometry, LAAS), by fluorescence detection (laser-induced fluorescence spectroscopy, LIFS), or by means of ionization products (electrons or ions) of the selectively excited analyte atoms after an appropriate ionization process (**Figures 1A and 1B**). Ionization can be achieved in different ways: (1) by interaction with an additional photon of the exciting laser or of a second laser (resonance ionization spectroscopy, RIS, or resonance ionization mass spectrometry, RIMS, respectively, if combined with a mass detection system); (2) by an electric field applied to the atomization volume (field-ionization laser spectroscopy, FILS); or (3) by collisional ionization by surrounding atoms (laser-enhanced ionization spectroscopy, LEIS).

Since its commercial availability, the laser has been used extensively as a source of powerful radiation. If the laser radiation is focused on to a solid sample, a small volume of the sample material can easily be

ablated into vapor-phase constituents such as atoms, ions, and particles. Because of that laser ablation (LA) represents one of the most promising micro-probe techniques of direct vapor generation and solid sample introduction in conjunction with a number of different analytical techniques. In combination with inductively coupled plasma (ICP), LA enables the

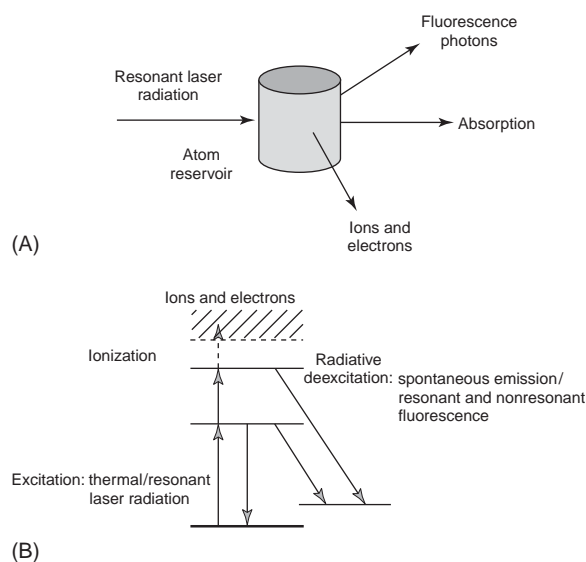

multielement analysis of solid samples by optical emission spectroscopic measurement (ICP-OES) or the ultimate trace analysis if coupled with mass spectrometric detection (ICP-MS). Ablated sample constituents that are excited in the laser plasma can be detected directly by emission spectroscopic techniques denoted as laser-induced breakdown spectroscopy (LIBS) or laser-induced plasma spectroscopy (LIPS).

The laser-based techniques commonly used in analytical atomic spectroscopy are summarized in Table 1.

The laser-based methods make use of different types of laser sources. Many of them, such as the solid-state laser or the semiconductor laser, are under continuous development because of the discovery of new lasing materials or the optimization of frequency conversion techniques. The type of the analytical application and the nature of the required information determine the choice of a special laser source, particularly pulsed or continuous-wave (CW) operating mode. Pulsed laser sources with fixed wavelength are usually used for LA, whereas both tunable pulsed and CW laser sources are preferred for element-specific detection or plasma diagnostics.

Some of the most frequently used laser sources in atomic spectroscopy and their typical parameters are listed in Table 2.

There is a whole range of other laser-based analytical techniques that are not within the scope of this

article, e.g., optogalvanic spectroscopy in flames or low-pressure discharges, and especially the numerous applications of molecular laser spectroscopy. The unsurpassed properties of commercially available lasers such as spectral brightness, small spectral linewidth, and variable pulse duration enable the improvement of existing methods and the development of new techniques of molecular spectroscopy not possible with conventional light sources.

The following examples of laser-based techniques and their relevant cross-references are summarized briefly for the sake of completeness. Some of the typical applications are:

- The absorption and fluorescence measurements of molecular gases with high spectral resolution by use of CW lasers or time-resolved spectroscopy with pulsed laser sources that enable the determination of the life time of short-lived excited molecular levels and radicals.
- The various techniques of Raman scattering that enable laser-based diagnostics of technical combustion processes as well as species identification on the micrometer scale or remote sensing of molecular species and pollutant in the atmosphere.
- Near-field optical microscopy in combination with Raman spectroscopy for the analysis of surfaces and interfaces and – because of the outstanding lateral resolution – for subcellular monitoring of molecular dynamics and single molecule detection.

- Photoacoustic spectroscopy and thermal lensing spectroscopy, which have proved to be very sensitive techniques for the detection of gaseous molecules.
- Matrix-assisted laser desorption and ionization process with mass spectrometric detection, which has been applied, for instance, for the identification of proteins and biological macromolecules.

An overview of important laser-based techniques in molecular spectroscopy is listed in Table 3.

## Radiation Sources for Laser Ablation

So far the most commonly used radiation sources for LA has been the Nd:YAG laser operating at the fundamental wavelength of 1064 nm. The advantages of this laser are good beam quality and a high degree of reliability. In principle, different types of lasers with a variety of wavelengths can be used for sampling, provided they deliver sufficient pulse energy. There has recently been a trend toward laser sources, which emit in the shorter wavelength region because of greater absorption of ultraviolet (UV) laser radiation by most solid materials and less absorption by the plasma formed above the sample surface. Both enable more efficient coupling of laser energy to the solid sample. Because of this the lasers most widely used nowadays for LA in spectrochemistry are the Nd:YAG lasers operated in the fourth harmonic (266 nm) and different types of excimer lasers such as ArF (197 nm), KrF (248 nm), or XeCl (308 nm).

**Table 3** Selected examples of laser-based techniques in molecular spectroscopy and typical applications

Absorption spectroscopy/ fluorescence spectroscopy	Detection techniques with high spectral resolution (tunable CW lasers). Most sensitive with multipass absorption cells and intracavity absorption. Measurements of chemical reaction diagnostics, lifetimes, and relaxation processes with high temporal resolution (pulsed lasers). Used also in combination with capillary electrophoresis and capillary chromatography
Raman spectroscopy	Makes use of various types of inelastic light-scattering phenomena such as spontaneous and stimulated Raman scattering induced by CW or pulsed laser sources. Diagnostics of combustion processes with high spatial and temporal resolution by coherent anti-Stokes Raman scattering (CARS). Structural analysis of polymers and biological compounds with high lateral resolution by laser Raman microanalysis (LRMA) or with lateral resolution below the diffraction limit in combination with scanning near-field optical microscopy (SNOM)
Remote sensing	Evaluation of various scattering processes (such as Mie, Rayleigh, Raman scattering, and resonance fluorescence) induced by the propagating of one or two pulsed laser beams. Mapping of trace constituents and pollutants in the atmosphere or measurement of meteorological parameters by LIDAR techniques (light detection and ranging)
Photoacoustic spectroscopy	Measurement of the photo- (or opto-) acoustic signal following the partial nonradiative dissipation of laser radiation absorbed by one or more compounds in a gaseous or liquid medium. Detection of ultralow concentrations of impurities. Used also in combination with gas and liquid chromatographies
Thermal lens spectroscopy	Evaluation of the transverse temperature profile ('the thermal lens') induced by laser radiation passing an absorbing (liquid) medium. Optical detection of organic compounds by the change of refractive index
Ionization spectroscopy	Dissociation and ionization by means of one or several lasers. Sensitive detection of fragments and ions with resonance photoionization and mass spectrometric techniques (tunable lasers). Matrix-assisted laser desorption/ionization mass spectrometry (MALDI) with pulsed ablating laser sources. High lateral resolution enables molecular microprobing of biological cell compounds

The main advantage of LA is the direct ablation capability from preselected areas of a sample, thereby avoiding laborious sample preparation and contamination. The focal spot size achieved with UV lasers of adequate (Gaussian) beam profile can be reduced to a few micrometers or less, which enables the microanalysis of solids. Quasicontinuous sampling is possible if the laser is operated with an adequate repetition rate.

## Tunable Laser Radiation Sources

If the laser is used as the primary excitation source the most important prerequisite is the tunability, which is the facility of preselecting the laser wavelength. To yield an appropriate tuning range, the lasing medium should have a wide gain profile. Soluble organic dyes such as rhodamine or coumarin are well suited for this purpose since they show strong absorption bands in the visible part of the spectrum, thus enabling optical pumping by means of flash lamps or other pump lasers. Solid-state lasers such as the optically pumped titanium-sapphire laser are also of increasing importance because of their broad tunability. The semiconductor diode lasers (DLs), on the other hand, which are commercially available nowadays, represent a fascinating excitation source combining compact size, reliability, low cost, and ease of handling. These qualities ensure

that such lasers are increasingly employed in the fields of plasma diagnostic and high-resolution spectroscopy.

As well as tunability, the radiation power delivered by the laser source is a characteristic parameter. In the case of high peak laser power, nonlinear optical effects can be utilized to expand the tuning range, predominantly into the short wavelength region. For this purpose one has to consider nonlinear optical processes, which are based on the interaction of high-intensity laser radiation with an appropriate optical medium. Well-known techniques in this respect are frequency doubling of the fundamental laser radiation, performed by means of second harmonic generation (SHG) in anisotropic crystals, Raman shifts in gases (like  $H_2$ ), or mixing techniques using two laser beams, which generate the sum or the difference frequencies of the exciting lasers. The efficiency of the nonlinear optical effects mentioned above varies quadratically with the laser intensity or with the product of the radiant power of the contributing lasers.

## Pulsed Dye Lasers

The properties of pulsed dye lasers are determined by the dye as well as by the nature of the pumping source. Common to all dyes is their broad amplification profile. By proper selection of dyes (which easily can be exchanged by a closed-loop design of

the dye flow circuit), the laser wavelength can be varied continuously within the range from  $\sim 350$  to  $1000$  nm. The spectral bandwidth of the laser radiation is usually confined (in commercial laser systems to  $\sim 1$  pm) by dispersive optical elements in the laser resonator, such as gratings and wavelength-selective transmission filters (etalons). This ensures the high selectivity that is essential for the excitation of atomic dipole transitions. Wavelengths below  $350$  nm are accessible by SHG, which is very effective because of the high peak power of  $\sim 1$ – $10$  MW, available in a single laser pulse. Frequency doubling techniques are restricted by the transmission of the nonlinear optical material to a shortest wavelength of  $\sim 210$  nm. In this way, most elements can be analyzed by making use of their most sensitive transitions.

Depending on the pumping source (either flash-lamps or other laser systems, such as excimer, Nd:YAG, nitrogen, or copper vapor lasers), the repetition rate of the dye laser can be varied between  $\sim 10$  Hz and as high as a megahertz. It is obvious that at low repetition rates only a small fraction of analyte atoms, which pass the interaction volume, is irradiated by the laser. This restricts the detection limit of the measurement, in particular if only small amounts of sample material are available, as in microanalysis.

### Tunable Solid-State Lasers

The pulsed dye lasers tend to be complex and have several shortcomings such as the use of toxic solvents and the relatively short lifetime of the dyes. For this reason these systems are gradually replaced by tunable solid-state laser systems. Their tuning range varies widely depending on the choice of the implanted ions and the host material. The tuning range of the titanium-sapphire laser ( $\text{Ti}^{3+}:\text{Al}_2\text{O}_3$ ), for instance, is typically  $720$ – $950$  nm. The output power, frequency stability, and linewidth of the titanium-sapphire laser are comparable with or superior to the dye laser. Repetition rates in the kilohertz range are available if pumped with a pulsed source such as a diode-pumped solid-state laser.

The wavelength region below  $720$  nm cannot be accessed directly by the titanium-sapphire laser but is covered by another laser system, e.g., the optical parametric oscillator (OPO). The OPO system consists of a birefringent crystal, e.g., BBO ( $\text{BaB}_2\text{O}_4$ ), placed within an optical cavity irradiated by an intense pump beam such as a Nd:YAG laser that is operated at its third harmonic ( $355$  nm). Through nonlinear interaction the pump beam is split into an idler beam and a signal beam, which generate a

signal beam tunable within the wavelength range of typically  $410$ – $710$  nm. This wavelength range can be extended significantly by additional frequency mixing techniques. To cover the same region with a dye laser, several dyes would be required.

### Continuous-Wave Dye Lasers

CW dye lasers are generally pumped by an argon ion laser. The tuning range of the CW dye lasers covers the wavelength interval  $260$ – $950$  nm, including frequency doubling, and is somewhat smaller than that of pulsed dye lasers. The most important feature of CW dye lasers in spectrochemistry is their very narrow spectral line width, which in the case of mono-mode operation and frequency-stabilized lasers is  $\sim 1$  fm (i.e.,  $10^{-15}$  m), and is thus smaller by three orders of magnitude than the linewidth of pulsed laser systems. Since the laser linewidth is even narrower than the Doppler profiles of spectral lines, this allows experiments of Doppler-free spectroscopy, which overcome the limitation of thermal broadening of spectral lines. The radiant power delivered by the CW dye lasers in mono-mode operation is typically less than  $1$  W. If one considers the laser linewidth, however, the spectral radiance is sufficient to excite optical transitions effectively. Another advantage of CW dye lasers is the long interaction time of analyte atoms in the radiation field, which yields improved detection limits.

### Semiconductor Diode Lasers

The disadvantage of all dye lasers is their complexity, their physical size, and their costs, which preclude the adoption of these systems for routine analysis. Semiconductor DLs, however, meet the requirements of practical spectrochemical analysis. They are small, reliable devices, which do not need to be aligned and have very stable power output. Produced on a large scale (as the scanning device in compact disc players), the costs of semiconductor DLs have been greatly reduced.

In contrast to the dye lasers mentioned above, lasing of the DL is accomplished easily by an electric current, which is sent in a forward direction through the p–n junction of the diode. The range of the laser wavelengths is determined by the semiconducting material, see Table 2, and comprises  $420$ – $570$  nm for InGaN,  $630$ – $730$  nm for InGaAlP/InGaP, and  $720$ – $860$  nm for AlGaAs/GaAs. Recently, the wavelength range has been further expanded by the development of GaN lasers, which emit wavelengths in the region  $360$ – $425$  nm. In general, wavelength tuning can be controlled by a computer and is performed by variation of the diode current as well as of the

temperature of the semiconductor. The DL can be tuned continuously within typically 0.05–0.1 nm. Tuning beyond this limit causes the laser to operate in another longitudinal mode ('mode hopping') with a further region of continuous tuning. The wavelength gaps, occurring between mode hopping, can be covered by additional DLs, which have been selected with regard to their spectral properties.

Because of the restricted spectral range covered by the fundamental wavelength of DLs commercially available nowadays, only a limited number of elements can be analyzed using their most sensitive resonance lines. Other elements of the periodic table, which have their most sensitive lines in the UV region, have to be excited by use of weaker transitions or by frequency doubling. This can easily be achieved yielding up to 1–10  $\mu\text{W}$  radiant power, whereas the radiant power of the fundamental wavelength emitted in the visible is in the range 50–100 mW.

The semiconductor DLs can be operated not only in the CW mode but also in a pulsed mode, e.g., as a pump source for solid-state lasers, or can be modulated at frequencies up to the gigahertz range by modulation of the diode current (see section on Laser-induced plasma spectrometry).

## Methods of Atomic Laser Spectrochemistry

Before spectroscopic techniques can be applied to elemental analysis, the sample has to be atomized effectively. Thus, the commonly used atomization sources such as flames, electrothermal atomizers (e.g., filaments or graphite furnaces), and ICPs are also prerequisites for the laser-based techniques of atom spectrochemistry. In addition, atomization by LA or electrothermal evaporation in low-pressure gas atmospheres should also be considered. The atomization source must be optimized with regard to efficiency, stability, uniformity, and chemical interference in order to obtain the best analytical results.

### Laser-Induced Plasma Spectrometry

The commercial laser sources used for LA ensure an irradiance typically  $>1 \text{ GW cm}^{-2}$ , far above the breakdown threshold, which is  $\sim 10^7 \text{ W cm}^{-2}$  for many materials. The nanogram to microgram amounts of sample material ablated with an individual laser pulse are effectively atomized, excited, and partially ionized in the hot plasma generated by the breakdown. Analyte atoms and ions can then be detected either by monitoring the spectral emission of the laser-induced plasma (LIPS, LIBS) or by the measurement of absorption, fluorescence, or

ionization signals that come into being if the laser radiation of properly selected wavelength intersects the plasma.

The plasma formation and excitation of sample atoms are complex processes, which are affected by the working parameters of the laser, the type of the sample material, and the ambient atmosphere. The mass removal and the plasma temperature, for example, have to be controlled carefully because they are affected by the sample composition. The calibration step requires, therefore, the use of matrix-matched standards, which are not always available. To correct for small variations of ablated mass and plasma temperature the signals from the analyte and a common matrix element are measured simultaneously applying the technique of the internal standard.

During the laser-surface interaction with lasers of nanosecond pulse width the material is removed mainly by an explosion-like evaporation from the overheated spot of the sample. The disadvantage of nanosecond lasers for accurate chemical analysis is the predominantly thermal character of the ablation process. As a consequence, fractionation may occur during the laser pulse depending on the sample and laser properties. Ideally, the entire laser-irradiated volume would be ablated without melting of adjacent sample regions and the ablated mass would represent the stoichiometric composition of the sample. With femtosecond pulse duration the deposition of the laser energy to the sample is so rapid that thermal effects can be clearly reduced or totally avoided. Femtosecond solid-state lasers with pulse duration of 100–200 fs are commercially available nowadays and are the basis for material processing on nanometer scale as well as for spectrochemical analysis with reduced matrix effects and improved lateral and even depth resolution.

**Applications** Since the laser plasma can excite the emission of all the elements ablated from the sample, LIBS has the potential for simultaneous multielement analysis. Typical applications are the rapid characterization of scrap and plastics prior to recycling, the minor or trace element detection for the bulk analysis of alloys, minerals, ceramics, or glass, the micro-sampling for pigment identification in artwork or geological inclusion chemistry, the compositional mapping of steel or of metal impurities in silicon wafers, and the *in situ* surface or depth analysis of technical coatings. If the laser radiation as well as the radiation from the plasma emission are transmitted by an optical fiber link, LIBS can be utilized for rapid noncontact sampling as in the online analysis of steel melt, for characterization of soils and ores with field instruments, or for remote sensing in hazardous

environments. Recently, the determination of  $^{239}\text{Pu}/^{240}\text{Pu}$  isotope ratios by LIBS was demonstrated using high-resolution emission spectrometry.

### Laser Atomic Absorption Spectrometry

Atomic absorption spectrometry (AAS) is a simple and reliable analytical method, but limited by a rather low dynamic range of about two orders of magnitude and by the fact that only one element can be analyzed at a time. These drawbacks can be overcome by LAAS if a tunable laser is used as the primary radiation source and if the hollow cathode lamp (HCL) is replaced by a DL. With regard to stability and spectral linewidth, the DL exceeds the specification of the HCL. Because of the high spectral radiance of the laser source, as compared to the background radiation from the atomizer (flame or graphite tube), no dispersive element such as a monochromator or a filter is necessary, and the collimated laser radiation (beam diameter typically 1 mm) is monitored by a low-cost semiconductor photodiode. The typical linewidth of the DL is  $\sim 30$  times less than the atomic linewidths that are observed in room temperature atom reservoirs (low-pressure plasmas, HCL) and two orders of magnitude less than the linewidths found in atmospheric pressure flames or graphite tubes. This allows the expansion of the linear dynamic range into higher concentration of an analyte if the laser wavelength is tuned precisely to the wing of the absorption profile, thus reducing the optical thickness, without changing to another less-sensitive absorption line. The wavelength of the DL can be easily modulated at frequencies up to gigahertz by modulation of the diode current. The wavelength modulation provides an effective correction of nonspecific absorption if the laser wavelength is switched from resonance to the background next to the absorption line and enables greatly improved limits of detection.

Simultaneous multielement LAAS can be performed if the radiation from several DLs is passed through the absorbing volume after alignment to a collinear beam by means of optical fibers or mirrors. The radiation of each laser is tuned separately to an absorption line and modulated in amplitude by an individual frequency. The absorption signals of different laser wavelengths are integrated at the common photodiode and evaluated by Fourier analysis.

**Applications** The potentials of DL-AAS have been demonstrated by measurement of trace metals in various atom reservoirs such as analytical flames and graphite tube furnaces. The limits of detection are typically two orders of magnitude lower than with

conventional AAS using HCLs. Absorbances of smaller than  $10^{-6}$  have been achieved with the double modulation approach when both the source and the absorption process are modulated, thus eliminating completely background signal and baseline drift. DL-AAS offers, moreover, a promising alternative as an element-selective detector for gas chromatography or liquid chromatography techniques. Elements that cannot be measured by conventional AAS with HCL such as hydrogen, oxygen, sulfur, noble gases, and halogens have been detected by coupling a gas chromatographic unit to a low-pressure plasma. DL-AAS can be utilized for elemental speciation as has been demonstrated by the detection of Cr(III) and Cr(VI) species in water using a commercial high-performance liquid chromatography unit. The limits of detection of  $0.5 \text{ ng ml}^{-1}$  observed for Cr(VI) are quite comparable with detection limits obtained with ICP-MS. Isotope selective analysis by DL-AAS of elements with isotope shifts larger than the Doppler broadening of the spectral lines has been demonstrated on the detection of isotopes of light and heavy elements such as Li, Pb, and U in low-pressure atomizers, where the pressure broadening is small.

### Laser-Induced Fluorescence Spectrometry

LIFS serves as a sensitive monitor for the selective absorption of laser photons as in LAAS. Since the LIF measurement reflects the population of the excited atomic state of analyte atoms it is well suited to gain information about competing transitions and collisional excitation or deexcitation processes. Compared with LAAS, LIFS techniques offer the advantage of a large concentration range of four to five orders of magnitude and low detection limits, particularly with CW tunable lasers. For weak radiation fields, such as in conventional sources, the fluorescence intensity is proportional to the source irradiance. In contrast to this, for a strong laser radiation field, the absorption of the laser radiation and consequently the fluorescence intensity is no longer linear. In this case the transition can be saturated by the exciting radiation field and the fluorescence intensity is entirely independent of the irradiance of the laser source. Consequently, fluctuations of the laser output do not affect the stability of the LIF signal. Moreover, radiative transition rates are usually some orders of magnitude greater than collisional depopulation rates due to quenching in a surrounding gas. This allows measurements to be made on atmospheric pressure sources, like flames, with good detection limits. Since saturation of the resonance transition can be attained most easily by pulsed laser sources, in this case the total number of fluorescence photons is

limited mainly by the laser pulse length and by the duty-cycle of the laser. If the measuring time is not restricted by the amount of available sample material, pulsed laser systems can also yield good analytical results if the fluorescence intensity is integrated over an appropriate number of single laser shots. In this case, however, it is essential to have a stable and reproducible atomization source.

Detection of analyte atoms with a more complex transition scheme requires the careful selection of the most favorable fluorescence transition, particularly if competing branching transitions are to be considered. Because of the high irradiance of the laser source scattering of the laser radiation on optical surfaces or on incompletely evaporated sample material deteriorates the detection limit of LIFS. The contribution of scattering can be neglected entirely if nonresonant fluorescence transitions are measured, which originate in branching transitions or in levels that have been populated by collisional transfer.

**Applications** The great potential of LIFS for diagnostics on spectrochemical excitation sources and atomizers, preferentially when using pulsed dye lasers, enable the measurement of various important spectroscopic quantities, such as transition lifetimes, collisional coefficients, and quenching rates. Tunable narrowband CW lasers, however, allow the determination of the profile and shift of spectral lines, thus yielding the excitation temperature, electron number density, and information about the different processes responsible for the observed line broadening. The analytical applications make use of the unsurpassed sensitivity of LIFS, especially in combination with electrothermal atomizers, such as the graphite tube furnace or the tungsten filament. The detection limits obtained with the analysis of metal traces in environmental samples or in biological liquids (e.g., Pb, Pt, Se in blood or serum) are in the nanogram per gram to picogram per gram range or even better. LIFS has also been applied to the determination of lithium and uranium isotopes in solid samples using a Nd:YAG laser for LA, and a pulsed tunable dye laser or a CW DL for excitation.

#### **Intracavity Absorption and Cavity Ring-Down Spectroscopy**

The sensitivity of AAS measurements can be increased significantly by increasing the absorption pathlength. A very effective multipass system can be achieved if the collimated radiation of a tunable laser is used as the primary light source. If the absorbing medium is placed inside the resonator cavity of the laser the sensitivity of the absorption measurement

can be enhanced considerably due to the multiple pass of the laser radiation within the resonator. For analytical purpose the intracavity absorption is measured by means of LIFS or by monitoring the output power of the laser, which is particularly advantageous, if the laser is operated near to the threshold level.

Cavity ring-down spectroscopy (CRS) is based on the measurement of the time constant for a laser pulse to decay inside an optical cavity consisting of two highly reflective dielectric mirrors. The laser pulse is injected through an end mirror of the cavity where it remains trapped between the mirror surfaces. The intensity of the laser radiation in the cavity as measured by a photomultiplier tube decays exponentially with time at a rate determined by the round trip losses experienced by the laser pulse. If absorbing sample atoms fill the optical cavity the decay time constant is reduced further because of the cavity losses originating from selective absorption of the sample following the Beer-Lambert law. Other sources of cavity losses like scattering can be determined easily by measuring the ring-down time with atomizer on and without analyte present.

**Applications** So far, intracavity laser spectroscopy has been applied primarily to the detection of absorption spectra of gaseous impurities such as  $\text{NH}_3$  and  $\text{CH}_4$  in the near-infrared region using a tunable broadband laser. Special DLs designed with an external cavity have also been investigated recently for this purpose. CRS has been applied successfully to trace element detection using the ICP as the atomization system. The detection limits observed are at sub-parts per billion level (e.g.,  $0.3 \text{ ng ml}^{-1}$  for lead) and comparable to the detection limits achieved with ICP-MS.

#### **Ionization Spectroscopy**

The strong radiation of laser sources enables the excitation of analyte atoms into high energetic levels just below the ionization limit. Ionization can then be accomplished by additional photons, by collisions, or by an external electric field (**Figure 2A**). In most cases the energy of one laser photon is not sufficient to ionize the ground state atom in a single step; ionization, therefore, has to be performed stepwise either by nonresonant multiphoton or by resonant ionization via a strong transition by use of a second or third tunable laser. The technique of stepwise resonance ionization by photons of different laser energy noticeably enhances the selectivity of the measurement by some orders of magnitude. This is essential if the ion contribution from matrix elements

**Figure 2** Excitation schemes of several laser ionization methods applying two- or three-step ionization with one, two, or three tunable lasers with different wavelength. In LEIS the final step of ionization is achieved by the thermal energy  $kT$  provided by collisional excitation (A), whereas in RIS the ionization is achieved with laser photons (B–D).

needs to be reduced, particularly in LEIS and RIS measurements without preceding matrix separation. Generally, ionization spectroscopy is one of the most sensitive detection techniques, provided that the ionization probability is high and the collection efficiency of the electrons or ions is nearly complete.

**Laser-enhanced ionization spectroscopy** LEIS makes use of the collisional ionization of analyte atoms that have been excited by resonant one- or two-step laser radiation close to the ionization limit. The ionization energy of the order  $kT$  can be raised by thermal collisions in chemical flames or in the surrounding buffer gas atmosphere. If the laser is tuned to a resonance transition of the atom the electrons and ions following the ionization step can be detected by two collecting electrodes, between which a voltage of  $\sim 1\text{--}2\text{ kV}$  is applied. In LEI spectrometry on flames the electron current is detected. This is because of the higher mobility of the electrons, which yield sharper analytical signals in the case of pulsed excitation. Different electrode configurations (plates, rods, water-cooled electrodes) have been tested.

**Field-ionization laser spectroscopy** The techniques of FILS are performed on collimated atom beams of an electrothermally evaporated sample. One or two pulsed laser beams traverse the beam of atoms, which are excited into high-lying Rydberg states by a one- or two-step excitation process. A high-voltage pulse, coinciding with the laser pulse, is applied to the electrodes, which are passed by the atom beam. If the field strength is properly chosen (depending on the effective quantum number  $n'$ ), a field gradient of  $\sim 400\text{ V cm}^{-1}$  is sufficient for complete ionization of analyte atoms with  $n' \gg 30$ . The ions are extracted from the atom beam by the same electric field pulse and measured by an ion detector.

**Resonance ionization spectroscopy** The ionization energy of most of the elements can be supplied only by two or more laser photons. To make use of the techniques of resonant ionization spectroscopy (RIS) ground-state atoms are excited via a dipole transition, which can be saturated easily. In the case of the single-laser excitation, an additional photon of the same laser can ionize the excited atoms (Figure 2B). High-intensity pulsed laser sources are needed for the efficient ionization, since the photoionization cross-section is less than the cross-section for the resonant absorption from the ground state by about five orders of magnitude. The single-laser resonance ionization process, however, may reduce the selectivity of analysis if off-resonant multiphoton excitation and ionization have to be considered. The transition rates for off-resonant two-photon ionization are rather small, but matrix atoms may contribute significantly because of their large number density, particularly in the case of trace analysis. To improve the selectivity, excitation processes with two or even three lasers with different wavelengths need to be considered. For this purpose the first excitation step is performed resonantly by a high-energy photon with moderate laser intensity. The succeeding excitation and ionization steps can be accomplished by low-energy photons of a second tunable laser with high radiant flux (Figure 2C). The selectivity can further be increased if the ionization is performed by a third laser (Figure 2D). This can be either a fixed wavelength laser with low photon energy, but high radiant flux (e.g.,  $10\text{ }\mu\text{m}$  of a  $\text{CO}_2$  laser) or a tunable laser of low intensity, if the wavelength is tuned to an autoionizing state. The third laser may have only moderate radiant flux, since the transfer rates for photoionization exceed the transfer rates for photoionization by two or three orders of magnitude.

For monitoring electrons or ions, RIS techniques make use of ionization chambers, ion multipliers, or

proportional counters as ionization detectors, which yield a nonselective analytical signal. The selectivity can be improved significantly by RIMS techniques, where a mass spectrometer is placed between the ion source and the ion detector. For this purpose a quadrupole mass filter can be used or a time-of-flight mass spectrometer, respectively, if the photoionization is performed by a pulsed laser. Spectrometers with high mass resolution, on the other hand, such as sector field instruments, offer the advantage of isotopic analysis.

**Applications** Although LEIS offers low detection limits, its application is somewhat restricted. This is due to quenching by molecular species in the flame or by matrix effects, which are introduced by accompanying elements with low ionization energy (such as alkali metals). Quenching can be avoided by use of an electrothermal atomizer such as a graphite tube furnace instead of a flame. Matrix interferences have been reduced by temperature programming of the electrothermal atomizer yielding a detection limit for lead in blood, for example, in the picogram per gram range. The coupling of LEI detection to flow-injection techniques has also been reported.

Because of their low absolute detection limits and their high selectivity, RIS and RIMS techniques have found important applications in the field of ultra-trace detection of metals in biological, environmental, and geological samples including single atom detection as has been proved with mercury atoms. The capability of the resonance ionization techniques was demonstrated on the isotope-selective detection of  $^{90}\text{Sr}$  in solid strontium samples combining the high sensitivity and high resolution of RIS with low-cost DLs and a low-resolution quadrupole mass filter. This technique was shown to be both spectroscopically and mass selective and by that advantageous over traditional ionization methods for atomic mass spectrometry since isobaric interferences, such as  $^{90}\text{Zr}$  or doubly ionized  $^{180}\text{Ta}$  and  $^{180}\text{W}$ , are reduced.

### Isotope-Selective Elemental Analysis by High-Resolution Laser Spectroscopy

The isotope-selective analysis by optical detection methods is almost impossible unless transitions with sufficiently large isotope shifts as observed with light and heavy elements are available. In contrast to traditional emission or absorption techniques the high-resolution laser spectroscopy enables Doppler-free measurements since the spectral linewidth of tunable CW lasers is commonly less than the Doppler profile

of the absorption lines introduced by the thermal velocity distribution of the atoms in the atomizer. A basic requirement for Doppler-free spectroscopy is the suppression of additional broadening effects, which implies that the analyte is atomized into vacuum or under low gas pressure. Typical applications are measurements on collimated atom beams or two-photon techniques, which are confined to an ensemble of atoms of uniform velocity.

#### Spectroscopy on Collimated Atom Beams

If a collimated atom beam expands into vacuum, the velocity component of the atoms in the beam direction is much greater than the thermal velocity component perpendicular to the beams axis, in accord with the low divergence of the beam. Consequently, the Doppler width of atom transitions, as seen by an intersecting laser field perpendicular to the axis of the atom beam, is reduced significantly. Isotopes, which have been excited selectively by the tunable laser, can then be detected by LIFS, by ionization techniques, such as RIS and FILS, or by RIMS after photoionization. LEI spectroscopy cannot be applied since collisional ionization does not occur in the atom beam.

#### Saturation Spectroscopy

Doppler-free profiles of spectral lines can be achieved by the method of saturation spectroscopy. The radiation of a tunable laser is split into two counter-propagating beams, which intersect a volume of absorbing atoms. The first strong pump beam saturates an optical resonance transition yielding the maximum population of the excited level, while the second weaker laser beam probes the remaining ground-state atoms. If the laser is tuned to the center of the resonance line, the absorbing medium is bleached and the probing beam cannot be absorbed. Tuning the probe laser across the absorption profile of the observed transition results in a narrow dip ('Lamb dip'), which has a width much smaller than the Doppler width. This enables the spectral resolution of transitions even when their Doppler profiles overlap (Figure 3). The method of saturation spectroscopy has been demonstrated on low-pressure gas discharges by LEIS techniques, where the change of plasma conductivity by the ionization products is detected.

#### Nonresonant Two-Photon Spectroscopy

Laser excitation of atoms can be achieved resonantly not only by one laser photon with appropriate energy, but also by nonresonant two-photon excitation, if the resulting photon energy equals the energy

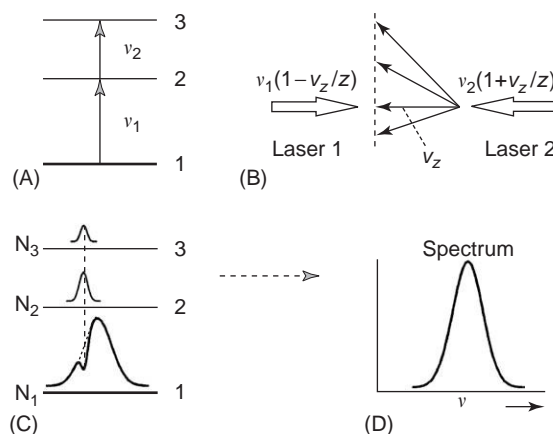

**Figure 3** Spectral separation of two Doppler-broadened profiles by saturation spectroscopy: (A) profiles of Doppler-broadened absorption lines with Lamb dips; (B) observed Doppler-free profiles (cross-over signals omitted).

of the dipole transition. The cross-section of nonresonant two-photon excitation is very low, as compared to resonance excitation. Since the transition rate is determined by the product of the intensities of the participating radiation fields, high-intensity lasers have to be used. If the laser radiation is focused, the interaction volume and thus the number of excited analyte atoms remains small, resulting in a poor detection limit. If only one laser source is available, the laser beam intersects the absorbing volume twice by means of a reflecting mirror. In this case atoms with a relative velocity component  $v_z$  in the direction of the laser beam, which see the laser frequency  $\nu_0$  Doppler-shifted by  $+\nu_0 \times (v_z/c)$ , can be further excited by a photon of the retrograding beam and the Doppler-shift is compensated by the corresponding component  $-\nu_0 \times (v_z/c)$ , and vice versa. This allows Doppler-free spectroscopy, since all atoms, which absorb photons from both directions, contribute to the analytical signal, irrespective of their velocity.

### Resonant Two-Photon Spectroscopy

In contrast to nonresonant two-photon excitation, the cross-section for resonant two-photon excitations is relative large if the atoms are excited via a strong resonance transition. To achieve resonant two-photon excitation, however, two tunable lasers are necessary with sufficiently narrow spectral bandwidths. The laser beams intersect the absorbing volume in co- or counter-propagating direction. If the first laser is tuned to the Doppler profile of the lower transition, atoms are excited with a well-defined velocity component in beam direction, whereas the second laser probes the population density of the excited atoms within this velocity group (**Figure 4**). The basic arrangement for isotope-selective analysis makes use of two absorption volumes, which are intersected by

**Figure 4** Principle of Doppler-free two-photon excitation: (A) resonant two-photon excitation steps; (B) frequencies of counter-propagating laser beams, as seen by atoms of the velocity component  $v_z$ ; (C) population densities of competing levels according to a well-defined class of velocity of analyte atoms; (D) resulting Doppler-free spectrum.

the laser beams simultaneously. In one absorption volume atoms with known isotopic composition are evaporated continuously. While the frequency of the first laser is locked to a line of an isotope, the second laser is tuned properly, yielding a Doppler-free spectrum of the isotopes in the second absorption volume. In this way isotope ratios can be determined optically if the first laser is switched in wavelength from isotope to isotope. The first atom reservoir is essential for fixing the laser wavelength, since the intensities of isotope components are strongly dependent on the frequency position of the first laser within the Doppler profile.

The spectroscopic methods described above have the disadvantage that not all excited atoms contribute to the analytical signal at the same time, but only those of a confined velocity group. This degrades the limit of detection; however, this can then be improved if efficient methods for ion detection are applied, such as LEIS combined with the thermionic diode. In the thermionic diode the ions are detected by means of the diode current, which is induced by charge effects with internal amplification by a factor of  $10^5$ – $10^7$ .

**Applications** Doppler-free high-resolution laser spectroscopy on low-pressure atom reservoirs and gas discharges allows the measurement of isotopic trace content and isotope ratios such as the determination of  $^7\text{Li}/^6\text{Li}$  isotope ratio, and thus offers the advantage of isotope dilution techniques for calibration.

## Introduction

Organolead compounds have been extensively used for many years as antiknock agents in gasoline. Although this use has been banned in developed countries, they are still in use in many developing countries. As a result, enormous amounts of these compounds have been, and still are, discharged into the atmosphere. Therefore, there is a significant

interest in understanding the origin, pathways, toxicity, and biological effects of organolead compounds in the environment. In order to properly identify organolead species, precise analytical methods capable of determining them at trace levels are necessary. The determination of individual organolead species requires the extraction and separation of the compounds, and their measurement with highly sensitive detection techniques that are able to perform analyses at the nanogram per liter level. During the last decades important advances were achieved in the development of hyphenated techniques for the analysis of organolead compounds, as well as in the production of certified reference materials for

## Introduction

Organolead compounds have been extensively used for many years as antiknock agents in gasoline. Although this use has been banned in developed countries, they are still in use in many developing countries. As a result, enormous amounts of these compounds have been, and still are, discharged into the atmosphere. Therefore, there is a significant

interest in understanding the origin, pathways, toxicity, and biological effects of organolead compounds in the environment. In order to properly identify organolead species, precise analytical methods capable of determining them at trace levels are necessary. The determination of individual organolead species requires the extraction and separation of the compounds, and their measurement with highly sensitive detection techniques that are able to perform analyses at the nanogram per liter level. During the last decades important advances were achieved in the development of hyphenated techniques for the analysis of organolead compounds, as well as in the production of certified reference materials for

the validation of the results. Lately, lead isotope ratios have been identified as an important tool for the study of lead contamination studies.

## Organolead Pollution

### Sources and Uses of Organolead Compounds

The massive use of lead in kitchen utensils and water pipes goes back to the period of the Roman Empire. Later on, the industrial revolution promoted its use on a global scale. However, it was the discovery of the antiknocking properties of the organolead compounds and the fast development of the auto industry in the last century that turned lead contamination

into a global problem. Tetraethyllead (TEL), tetramethyllead (TML), and, sometimes mixtures of methylated and ethylated organolead species, are added to gasoline to prevent the premature and spontaneous explosion of the air/gasoline mixture in the engine. Table 1 shows the different organolead species that can be found in the environment. The release of TML and TEL was drastically reduced with the introduction of unleaded gasoline in the late 1970s in the USA and followed by other parts of the world. However, leaded gasoline is still available in many countries and contributes to the emission of TEL and to a less extent TML into the environment. Besides the anthropogenic sources cited below, there is limited evidence that under some circumstances, natural methylation of lead salts may also occur.

**Table 1** Organolead compounds found in the environment

Compound	Name (abbreviation)
<b>Tetraalkyllead (TAL)</b>	
Me <sub>4</sub> Pb	Tetramethyllead (TML)
Me <sub>3</sub> EtPb	Trimethylethyllead (TMEL)
Me <sub>2</sub> Et <sub>2</sub> Pb	Dimethyldiethyllead (DMDEL)
MeEt <sub>3</sub> Pb	Methyltriethyllead (METL)
Et <sub>4</sub> Pb	Tetraethyllead (TEL)
<b>Ionic alkyllead (IAL)</b>	
<i>Trialkyllead</i>	
Me <sub>3</sub> Pb <sup>+</sup>	Trimethyllead salt (TriML)
Me <sub>2</sub> EtPb <sup>+</sup>	Dimethylethyllead salt (DMEL)
MeEt <sub>2</sub> Pb <sup>+</sup>	Methyldiethyllead salt (MDEL)
Et <sub>3</sub> Pb <sup>+</sup>	Triethyllead salt (TriEL)
<i>Dialkyllead</i>	
Me <sub>2</sub> Pb <sup>2+</sup>	Dimethyllead salt (DML)
MeEtPb <sup>2+</sup>	Methylethyllead salt (MEL)
Et <sub>2</sub> Pb <sup>2+</sup>	Diethyllead salt (DEL)
<i>Monoalkyllead</i>	
MePb <sup>3+</sup>	Methyllead salt (ML)
EtPb <sup>3+</sup>	Ethyllead salt (EL)

### Emission, Transport, and Partitioning of Organolead Compounds

TML and TEL are introduced into the environment through car exhaust fumes (~1% of the organolead content of the gasoline is expelled unchanged), evaporation losses from gas tanks and stations, and accidental spilling. Whereas vehicle emissions led to a ubiquitous distribution of low concentrations of organolead compounds and in greater amounts of inorganic lead in the upper layers of soil, spillages of highly toxic tetraalkyllead (TAL) compounds during production, transportation, or blending at oil refineries and petrol stations caused more severe soil and groundwater contaminations. Figure 1 shows the biogeochemical cycle of the organolead compounds.

In the atmosphere, TAL is decomposed photocatalytically by ultraviolet irradiation, by ozone, or by hydroxyl radicals to the more stable, water-soluble ionic tri- and dialkylated species. Monoalkyllead cations are assumed to be very unstable. The

**Figure 1** Simplified biogeochemical cycle for organolead compounds in the environment.

dialkyllead species are thermodynamically more stable, and are therefore the main lead species found in air samples collected far away from the anthropogenic sources. The enrichment of organometallics over the inorganic lead as the air mass is moving away from the source can be explained on the basis of the species residence times. The organolead species ( $R_4Pb$  and  $R_nPb^{(4-n)+}$ ) present in the vapor phase are scavenged less efficiently from the atmosphere than the inorganic lead present in the aerosol.

### Toxicity of Alkyllead Species

Due to their more covalent nature, and thus higher lipophilicity, organometallic compounds usually accumulate more efficiently and they are more toxic than the inorganic form of the metal. The toxicity of alkyllead compounds decreases in the sequence:  $R_4Pb > R_3Pb^+ > R_2Pb^{2+}$  (with  $R = -CH_3$  or  $-C_2H_5$ ), the methylated lead species being less toxic than the ethylated compounds. Thus, even though their stability is not high, the final toxicological impact of the organolead species is very important as they are much more toxic than inorganic lead. Minimal bioaccumulation was observed for TEL and TML in shrimps, mussels, and plaice.

Organolead compounds can be absorbed through the skin and the respiratory tract. Their lipophilic nature allows them to easily go through biological membranes of the organism by passive diffusion. Oxidative dealkylation catalyzed by cytochrome P-450 in the liver results in the formation of trialkyl metabolites and finally inorganic lead. These trialkyl species are transported by the blood to the kidney, muscles, and brain, leading to a great variety of physiologic disorders. After some weeks, these metabolites finally settle in bones and teeth. The acute toxicity of TEL and TML is moderate in mammals and high in aquatic biota.

### Techniques for the Determination of Organolead Compounds

The concentrations of organolead compounds found in the different environmental compartments are often in the  $pg\ m^{-3}$ ,  $ng\ l^{-1}$ , and  $ng$  per  $g$  levels for air, water, and sediment and biological tissues, respectively. However, inorganic lead forms can simultaneously be present in the same samples at a 1000-fold higher level. For this reason, the instrumentation necessary to carry out lead speciation analysis in real samples requires the isolation, separation, and sensitive detection of the individual organolead species in the presence of thousands of

matrix components. This goal is usually achieved by coupling powerful chromatographic techniques with sensitive and specific detection systems based on atomic detectors.

### Detection Techniques

Atomic absorption spectrometry (AAS) was established as the most popular gas chromatography (GC) detection technique for lead speciation analysis in the first years of speciation studies. The increase of the residence time of the species in the flame using a ceramic tube inside the flame and, later, the use of electrically heated tubes, made out of graphite or quartz where electrothermal atomization was achieved, provided lower detection limits but still not sufficiently low. Later, the boom of plasma detectors, mainly microwave induced plasma atomic emission (MIP-AES) and, above all, inductively coupled plasma atomic emission and mass spectrometry (ICP-AES and ICP-MS, respectively) allowed the sensitivity requirements for reliable organolead speciation analysis in environmental and biological samples (typically subfemtogram levels) to be achieved. These sensitivity requirements makes speciation analysis of organolead compounds by molecular detection techniques such as electrospray mass spectrometry (ES-MS) a very difficult task and, therefore, the number of applications in the literature is very limited.

### Separation Techniques

Generally, GC is superior to liquid chromatography (LC) with regard to resolution, and very often in terms of separation time and sensitivity as well. This is especially true when an atomic detector is coupled to the chromatographic technique since LC requires a nebulization step whose efficiency is most often much less than 100%.

Prior to their separation by GC, organolead compounds need to be extracted from the sample matrix and, if necessary, derivatized into a volatile and thermally stable form. Volatile nonpolar tetraalkyl compounds can be extracted from environmental samples with nonpolar solvents such as benzene or hexane and injected directly onto the gas chromatograph. The case of nonvolatile, ionic alkyl compounds ( $R_2Pb^{2+}$  and  $R_3Pb^+$ ) is more complex. They should first be extracted and preconcentrated in the presence of NaCl and sodium diethyldithiocarbamate and then derivatized into a volatile form. The most widespread derivatization methods are of two distinct types: those based on the use of tetraalkylborates that can be directly performed in the aqueous solution (ethylation and propylation) and those applying

alkylation through Grignard reagents that requires nonaqueous media.

LC has not been so widely used for the determination of organolead species, although it does not require the derivatization of the analytes. The need for a nebulizer/spray chamber system usually restricts the detection limits achievable using standard LC. Almost all the methods use a reverse-phase column, and in some of the cases an ion-pairing reagent is added to the mobile phase. Several types of detection systems have been employed, such as AAS and ICP-AES, but the sensitivity of both approaches is disappointing. The coupling of LC with ICP-MS is the only means capable of detecting ultratrace levels of organolead species in typical environmental samples. The development of isotope dilution LC-ICP-MS has been successfully applied in the determination of TML and TEL in the presence of large amounts of inorganic lead in synthetic rainwater samples. An interesting alternative consists in the extraction of the organolead species in capillary tubing using solid-phase microextraction (in-tube SPME) and reversed-phased LC directly coupled to ES-MS allowing the detection of the molecular ions of TML and TEL (Table 2).

The use of supercritical-fluid chromatography (SFC) coupled to ICP-MS was applied for the separation and detection of TEL and tributyl lead acetate, although the apparent instability of tributyllead acetate under SF conditions and the presence of an additional peak when the mixture is injected does not favor its determination by SFC-ICP-MS. The use of SFC-ICP-MS for the quantification of TEL in SRM NIST 2715 'Lead in Reference Fuel' gave results in excellent agreement with the certified values.

In order to shorten the sample preparation steps, the use of a flow injection (FI) system for the continuous preconcentration of organolead compounds has been studied. It is based on a C<sub>60</sub> fullerene sorbent column and derivatization of the eluent analytes using a Grignard reagent prior to measurement by GC-MS.

Organolead speciation analysis has also been achieved by the use of modified silica capillaries following nebulization with a direct injection nebulizer (DIN), which is very suitable for the introduction of liquid samples into ICP-MS.

## Organolead Compounds in the Environment

It is estimated that ~1% of organolead in gasoline is emitted from vehicles in the form of TAL and ionic alkyllead. The presence of alkyllead compounds was confirmed in different types of environmental samples, such as air and rainwater, which contained organolead compounds in appreciable concentrations. The presence of organolead compounds in aquatic ecosystems, and especially in the marine environment, has not been studied extensively.

### Air

In the period 1970–90, considerable efforts were made to establish the fate of these compounds in air samples. At most urban sites, the typical contribution of organolead to total lead lies within the range 1–10%, with absolute concentrations in the range 10–200 ng Pb m<sup>-3</sup>, and a strong correlation with local gasoline could be observed in the composition of the atmospheric TAL. At roadside sites, the percentage of TAL to total lead is determined by the predominant driving mode; alongside motorways where vehicles drive at constant high speeds the TAL concentration can be from 5 to 10 times lower than at urban sites with interrupted traffic flows. The concentration of TAL decreases with an increase of distance from the road. In the vicinity of petrol (gasoline) stations a high percentage of TAL may be observed, mainly due to evaporative losses from spillage, and the displacement of TAL from fuel tanks. A high percentage of TAL has been found in enclosed car parks where vehicles are started from cold, with consequent inefficient fuel combustion and low engine temperatures. Measurements performed at rural sites are very scarce. For example, TAL concentrations were found to be below 0.1 ng (Pb) m<sup>-3</sup> in air samples collected from two rural sites near Beijing (China). In rural Denmark, TML concentrations were between 0.5 and 2.5 ng (Pb) m<sup>-3</sup>.

Organolead compounds can be associated with airborne particulate matter. A recent study determined the concentration of organolead in airborne particulate matter collected in Oviedo (Spain). The results show concentrations of 1.6–3.6 and 5.5–23.5 pg m<sup>-3</sup> DML and DEL, respectively.

**Table 2** Detection limits, expressed as ng (Pb) ml<sup>-1</sup>, for the determination of organolead species using different analytical techniques

Technique	TriML	DML	TriEL	DEL
GC-MS	0.6	1.2	0.4	0.8
SPME-GC-MS	0.13		0.08	
GC-MIP-AES	0.04	0.05	0.06	0.08
GC-ICP-MS	0.003	0.002	0.002	0.009
GC-ICP-TOF-MS	0.04	0.05	0.05	0.06
LC-ICP-MS	3		14	
SPME-LC-ESI-MS	11.3		12.6	

### Water, Snow, and Ice

Few measurements have been made of organolead compounds in natural waters. Apart from direct emission into waters, from fuel spillage or accident during transport, the tri- and dialkyllead decomposition products of TAL are quite soluble in water and so may be washed out by rain into surface waters. A survey of waters in Birmingham (UK) revealed concentrations of  $2 \mu\text{g(Pb)}\text{l}^{-1}$  of TAL in several road drainage grids. The analysis of runoff waters from the M6 motorway (northwest England) showed levels of TAL in the range  $0\text{--}36 \mu\text{g(Pb)}\text{l}^{-1}$ . Rainwater samples collected simultaneously at six sites in or near Antwerp (Belgium) were found to contain  $28\text{--}330 \text{ ng(Pb)}\text{l}^{-1}$  trialkyllead with an apparent correlation with local traffic density. Samples were also taken from surface waters and the trialkyllead concentration was found to be less than  $20 \text{ ng(Pb)}\text{l}^{-1}$ , except for road drainage waters from a highway ( $70\text{--}140 \text{ ng(Pb)}\text{l}^{-1}$ ). A lead speciation study in rainwater collected in central England shows that the total lead in rainwater has exhibited a strong decline since the 1980s because of the phasing out of gasoline lead, but the decline in organolead in rainwater is much less. A study performed during 1992–95 in Šibenik (Croatia) showed concentrations of  $37 \pm 28$  and  $2.7 \pm 2.3 \text{ ng l}^{-1}$  of organic lead in rainwater and seawater, respectively. These concentration levels correspond to 0.1% and 1.8% of total lead in rainwater and seawater, respectively.

Speciation analysis of organolead compounds was carried out in ice core samples collected in Greenland and on Mont Blanc. Organolead concentrations in the Greenland record ranged from 0.05 to  $0.5 \text{ pg per g}$ . The concentrations found show an increasing trend since the early 1970s until the beginning of the 1980s. In the Mont Blanc samples the measured concentrations ranged from 0.1 to  $3 \text{ pg per g}$  for DML, from 0.08 to  $3.4 \text{ pg per g}$  for TriML, from 0.01 to  $0.57 \text{ pg per g}$  DEL, and from 0.01 to  $0.13 \text{ pg per g}$  TriEL. No organolead concentrations were detected in ice deposited before 1962.

### Dust, Soil, and Sediments

Levels of tetra-, tri-, and dialkyllead were measured in street dust samples collected in 1976 in Lancaster (UK), and the concentrations ranged between 0.4 and  $7.4 \mu\text{g Pb g}^{-1}$ . With regards to the study carried out in Šibenik (Croatia), in contrast to the total lead ( $19.8 \pm 17 \text{ ng per g}$ ), organolead compounds were not found to be accumulated in sediments ( $0.2 \pm 0.2 \text{ ng per g}$ ).

Four organolead species (DEL, TriEL, DML, and TriML) were determined in a peat bog collected in

the Jura Mountains (Switzerland). The first quantifiable occurrence of organolead in this peat is from year 1943, and this agrees with the introduction of leaded gasoline in Switzerland.

### Biological Samples

In an extensive survey of fish from various lakes and rivers in Ontario (Canada) in the late 1970s, TAL compounds at levels of  $1\text{--}10 \text{ ng(Pb)}\text{g}^{-1}$  were found in  $\sim 16\%$  of the samples. All five TAL compounds were found. Samples of water, vegetation, algae, weeds, and sediments collected during the same survey did not contain TAL above the detection limits ( $0.1\text{--}0.5 \text{ ng(Pb)}\text{g}^{-1}$ ). A high concentration of trialkyllead was found in birds found dead or dying on the Mersey estuary (UK) in 1979. The analysis of the birds' invertebrate prey, bivalve baltic tellin and polychaete worms, also showed increased concentrations of trialkyllead species. Mussels and fish collected in Šibenik (Croatia) revealed a concentration of organolead compounds of  $6.1 \pm 12.1$  and  $0.9 \pm 0.9 \text{ ng per g}$ , respectively.

In mammals, inhalation or adsorption of TAL compounds results in the formation of trialkyllead in tissues and body fluids. With the exception of methylleads found in the blood of petrol workers, they are usually below the detection limits in blood and urine samples.

## Assessment of the Origin of the Organolead Pollution

### Record of Organolead Compounds in Environmental Archives

Lead released to the atmosphere consists of a complex mixture containing inorganic lead (natural and anthropogenic sources) and organic lead used in leaded gasoline. Thus, the determination of the total lead concentration is likely to be too simple for a reliable and definitive identification of the polluting source, since it is clear that the use of TAL in gasoline brought about an increase in lead industrial activities as well. Therefore, the determination of the organolead species seems to be the only valid way for assessing the contribution of gasoline to global lead pollution. In this way, the analysis of organolead species recorded by Greenland ice, high-altitude alpine snow, Swiss peat bogs, and old wine vintages allowed tracing the introduction, growth, and decline of the use of antiknocking agents in gasoline and their influence on the overall global and local environmental geochemistry of lead. In fact, no detectable concentrations for these compounds in samples predating the introduction of leaded gasoline

strongly suggest that natural sources of these species are negligible.

Moreover, the use of the configuration of the different organolead species in the sample (referred to as speciation pattern) may be used to obtain valuable information of the sample. For example, the DEL/TriEL and  $Pb_{org}/Pb_{inorg}$  ratios could help in assessing the age of the air masses transporting the species, the distance away from emission sources, and time spent over the ocean.

### Isotope Ratio Measurements

Lead isotope ratios can provide analytical information about sources of lead contamination whereas lead concentration measurements cannot. Due to this fact, studies of the isotopic composition of lead are commonly used in environmental science as well as in geological and anthropological studies. Among all of the naturally occurring lead isotopes only  $^{204}Pb$  is nonradiogenic, whereas  $^{206}Pb$ ,  $^{207}Pb$ , and  $^{208}Pb$  are daughter products from the radioactive decay of  $^{238}U$ ,  $^{235}U$ , and  $^{232}Th$ , respectively. This fact produces small Pb isotope abundance variations in nature, and it was observed that the isotopic composition of lead in environmental materials is clearly dependent on the ore deposits from which it came.

The differentiation between sources of lead organometallic compounds was recently accomplished using quadrupole ICP-MS. The measurement of lead isotope ratios by GC-ICP-MS of organolead standards allowed the differentiation between lead sources. The excellent precision of results obtained using a multicollector ICP-MS for lead isotope ratio

measurements by GC-ICP-MS is very promising for this kind of study.

In this way, characterization of the source of different organolead compounds in atmospheric particulate samples can be carried out by measuring lead isotope ratios for the various lead species. It is worth indicating that organolead species account for  $\sim 0.1\%$  of the total lead present in these samples. On the one hand, the glass fiber filters used in a standard high volume sampler were digested and the isotopic composition of total lead was measured by nebulization for ICP-MS using thallium as an internal isotope standard. On the other hand, organolead species were extracted and analyzed by GC-ICP-MS. Lead isotope ratios, measured for different organolead species present in these airborne particulates (DML, MEL, and DEL) and in leaded gasoline (TML, TMEL, DMDEL, METL, and TEL) collected in the same city, could be compared. The results obtained are illustrated in Figure 2. As can be observed, the isotopic composition of organolead species in the urban atmosphere was very close to that found in leaded fuel sold in the same city. On the other hand, total lead in these airborne particulates had an isotopic signature clearly different. Thus, the measurement of the isotope ratios in the organolead species allowed the influence of the leaded gasoline in the air pollution of the city under study to be traced whereas the measurement of the isotope ratios in the total lead failed to do this. Moreover, this speciated isotopic information greatly complements isotopic information on total lead, since it allows the direct and unambiguous identification of the origin of the

**Figure 2** Demonstration of the additional information provided by speciated isotope ratios for the analysis of total lead and organolead species in airborne particulate matter, and organolead species in leaded gasoline. Both types of samples were collected in Oviedo (Spain). Error bars correspond to one standard deviation.

pollution from leaded gasoline while the second one also allows the assessment of the contribution of the natural and industrial lead to the global lead contamination.

## Validation of the Analytical Methodology

### Certified Reference Materials

In order to improve the quality control of lead speciation analysis, two certified reference materials have been produced by the EC Measurement and Testing Programme. BCR CRM 604 (TriML in artificial rainwater) with a reference value of  $55.2 \pm 3.5$  ng per kg, and BCR CRM 605 (TriML in urban dust) with a reference value of  $7.9 \pm 1.2$  µg per kg. The latter is useful for testing the extraction and derivatization procedures in addition to the testing of the effect of large presence of inorganic lead. As an example, Figure 3 shows a GC-ICP-MS chromatogram of the CRM 605 material. As can be seen, a wide range of organolead species together with the certified TriML were detected (TEL was added as internal standard for quantification purposes).

### Isotope Dilution

An emerging area of interest in analytical chemistry is the use of isotopically labeled species for validating organometallic compound speciation analysis by means of a primary method of measurement such as isotope dilution analysis. The synthesis of the species using an isotopically labeled metal is a prerequisite. This unique way of quantification, based also

on isotope ratio measurements in each separate species, leads to valuable analytical advantages if the isotope equilibration between the isotopically labeled species and the incurred one is achieved. If so, any loss that occurs in the subsequent steps, nonquantitative separations during sample preparation and preconcentration, matrix effects and detector instabilities are totally compensated. Up to now, this innovative methodology has been applied to organolead speciation only using LC as a separation technique. For this purpose, TriML enriched in  $^{206}\text{Pb}$  was synthesized and applied for the accurate and precise determination of TriML in rainwater.

### Introduction

The domain of lipids comprises substances ranging from simple fatty acids to the complex phospholipids and from fat-soluble pigments and vitamins to sterols and steroid hormones. In the past these compounds have been frequently considered related mainly because of their mutual solubility in organic solvents and not because of their physical, chemical, or biochemical characteristics. Many of them, however, occur together in lipoproteins and cell membranes where they apparently form highly organized structures of a liquid crystalline type. It is now known that many lipid molecules are specifically bound by protein carriers, receptors, and enzymes. Faulty binding of lipids by carriers and receptors are known to lead to metabolic abnormalities and disease. It is obvious that the knowledge of complete lipid composition

will be necessary for the elucidation of the molecular relationships in lipoproteins and cell membranes in order to gain full insight and understanding of the normal metabolic and disease state of lipid metabolism.

Due to the chemical diversity of lipids, the major difficulty associated with any study of their chemistry or biochemistry has been that of isolation and separation into individual components. As a result, most advances in the understanding of lipid composition, structure, and function had to await the development of appropriate methodology. By the early 1960s new and improved procedures based upon the principle of chromatography had been forthcoming and had allowed a better fractionation and more complete identification of most lipids. The chromatographic efforts culminated in the development of combined or integrated thin-layer (TLC) and gas chromatography (GC) systems, which permitted an extensive resolution and quantification of many components of natural mixtures. During the next 40 years, both TLC and GC became complemented by high-performance liquid chromatography (HPLC) and by combinations of chromatography and mass spectrometry (MS), which further improved the certainty of identification and quantification of lipids

### Introduction

The domain of lipids comprises substances ranging from simple fatty acids to the complex phospholipids and from fat-soluble pigments and vitamins to sterols and steroid hormones. In the past these compounds have been frequently considered related mainly because of their mutual solubility in organic solvents and not because of their physical, chemical, or biochemical characteristics. Many of them, however, occur together in lipoproteins and cell membranes where they apparently form highly organized structures of a liquid crystalline type. It is now known that many lipid molecules are specifically bound by protein carriers, receptors, and enzymes. Faulty binding of lipids by carriers and receptors are known to lead to metabolic abnormalities and disease. It is obvious that the knowledge of complete lipid composition

will be necessary for the elucidation of the molecular relationships in lipoproteins and cell membranes in order to gain full insight and understanding of the normal metabolic and disease state of lipid metabolism.

Due to the chemical diversity of lipids, the major difficulty associated with any study of their chemistry or biochemistry has been that of isolation and separation into individual components. As a result, most advances in the understanding of lipid composition, structure, and function had to await the development of appropriate methodology. By the early 1960s new and improved procedures based upon the principle of chromatography had been forthcoming and had allowed a better fractionation and more complete identification of most lipids. The chromatographic efforts culminated in the development of combined or integrated thin-layer (TLC) and gas chromatography (GC) systems, which permitted an extensive resolution and quantification of many components of natural mixtures. During the next 40 years, both TLC and GC became complemented by high-performance liquid chromatography (HPLC) and by combinations of chromatography and mass spectrometry (MS), which further improved the certainty of identification and quantification of lipids

with high sensitivity. Thus, GC in combination with electron ionization MS (GC-MS) and HPLC with online electrospray ionization MS (LC/ESI-MS) became established as the definitive methods of lipid analyses. In recent years, the latter systems have become largely replaced by tandem mass spectrometry, which abandons the chromatographic step for speed and efficiency although at some sacrifice of resolution and quantification. In food and pharmaceutical industry, normal phase HPLC has been extensively replaced by packed column supercritical fluid chromatography (SFC), which has resulted in significant savings in solvents.

The present overview briefly considers the more successful applications of the individual methodologies in lipid analyses, the improvements brought about by their complementary combinations, along with the progress toward further resolution and more sensitive analyses. The overview concludes with a brief consideration of the lipid analyses demanded by lipidomics, and recent developments in proteomics and genomics.

## Types of Lipids Encountered

The common lipids are of two general types: neutral lipids and polar lipids. Both are esters of the common fatty acids, such as palmitate, stearate, oleate, linoleate, arachidonate, and docosahexaenoate, as well as others. The major neutral lipids are made up of the fatty acid esters of glycerol (mono-, di-, and triacylglycerols) and of cholesterol or other sterols. The triacylglycerols may contain one-, two-, or three different fatty acids per molecule, which are non-randomly distributed and give rise to a complex mixture of molecular species. The polar lipids consist of glycerophospholipids, which are mixed organic and inorganic acid esters of glycerol and sphingomyelins, which are derivatives of the base sphingosine. The natural glycerophospholipids represent a single enantiomer and contain either a fatty acid or an alkyl or vinyl ether at the *sn*-1-position and a fatty acid at *sn*-2-position, while the *sn*-3-position is occupied by phosphoric acid (stereospecific numbering). Also, esterified to the phosphate group is one of a series of polar head groups, which include choline, ethanolamine, serine, and one of several forms of the polyhydroxycyclitol inositol. The phosphate can also be esterified to phosphatidylglycerol resulting in four fatty acyl substituted glycerophospholipid (cardiolipin). Molecular species diversity in these phospholipids results from a pairing of different fatty chains in a glycerophospholipid molecule, with a saturated fatty chain usually occupying the *sn*-1 and an unsaturated fatty chain the *sn*-2-position. A

**Figure 1** Major neutral glycerolipids and glycerophospholipids. The general formula on the left depicts an *sn*-1-alkyl-2-acylglycerophospholipid with a head group  $X$ , which may represent  $H$ , as in GroPOH, choline, as in GroPCho, ethanolamine, as in GroPEtn, inositol, as in GroPIns, glycerol, as in GropGro or serine, as in GroPSer, all as *sn*-1,2-enantiomers. Substitution of the *sn*-1-alkyl and the *sn*-3 phosphoryl group with fatty acids gives a triacylglycerol, which upon removal of one or two fatty acids yields a diacyl- or monoacylglycerol, the isomer being determined by the acyl group removed. The three positions of the glycerol molecule may be substituted by one, two, or three different types of fatty acids yielding mixed acid triacylglycerols. Redrawn from Murphy and Harrison (*Mass Spectrometric Reviews* 13: 57–75. 1994).

reversal of this substitution results in reverse isomer formation. The sphingomyelins contain a long chain base of the sphingosine class. These phospholipids contain a fatty acyl group in an amide bond with the basic nitrogen atom of the long chain base and phosphocholine residue esterified to the primary alcohol group of the long chain base. Molecular species diversity in this phospholipid class results from a combination of various long chain bases with various common fatty acyl groups. Representative structures of the common glycerophospholipids are found in **Figure 1**.

## Historical Developments

The earliest attempts of lipid analyses are found in the isolation and identification of individual fatty acids, phospholipids, and triacylglycerols. Although a number of fatty acids were isolated and identified by purely chemical methods, such as metal salt formation, bromination, and crystallization, effective separation of fatty acids was first achieved by distillation, which permitted resolution of fatty acid homologs. Molecular distillation of fatty acids became a forerunner of their eventual resolution by GC. Likewise, chemical methods were used for the initial isolation of the naturally occurring glycerophospholipids as individual lipid classes or mixtures

of related phospholipid classes. Although it was recognized that all these preparations represented mixtures of molecular species, there were no means available that would permit their resolution. The early isolations of natural triacylglycerols were obtained by crystallization, which also led to mixtures of molecular species precipitating a debate, whether or not these preparations represented mixtures of single acid or mixed acid triacylglycerols. Sterols and steroids were isolated in relatively pure form by crystallization, although close isomers were not resolved until chromatographic methods became available.

The field of fatty acid separation was revolutionized by the development of GC, which allowed nearly complete separation of the common fatty acids. Later workers developed methods for GC separation of steroids, and of the steryl and glyceryl esters by high-temperature GC. The introduction of the flame ionization detector (FID) transformed GC from a method of qualitative separation into a method of quantification, which has remained unsurpassed to the present day. In parallel, TLC was developed as both a preparative and analytical technique for the resolution of the nonvolatile lipids. Because of the nearly universal applicability to all lipid analyses and the use of inexpensive apparatus, TLC made lipid separations accessible to all laboratories and it has remained unsurpassed as a method of sample preparation for modern analytical methods of lipid analyses.

## Current Methodology

High-performance TLC (HPTLC) has now largely replaced conventional TLC as a method of lipid resolution and quantification. Scanning of charred and radioactive spots provides improved quantitative estimates due to increased resolution of all components compared to conventional TLC. It serves as an efficient method of sample isolation for sensitive MS identification of various lipids. Modern TLC is a fully instrumental technique distinguished from conventional TLC. Because the technique is optimized to achieve maximum separation with high levels of automation, the results are largely independent of operator skill. Both one-dimensional and two-dimensional HPTLC are commonly employed. Normal phase TLC on Chromarods (latroscan) with FID constitutes a special application to separation and quantification of both neutral and polar lipid classes. The order of resolution of the lipid classes is directly related to the polarity of the solutes, which may be modified to some extent by the preparation of derivatives or altering the polarity of the adsorbent.

Various complexing agents may be incorporated into the adsorbent to permit improved resolution of saturated and unsaturated lipid classes and molecular species (silver nitrate) and the resolution of *vic*-hydroxylated and nonhydroxylated lipid classes (borate). A practical combination of HPTLC with MS, however, has not yet materialized. In contrast, normal phase HPLC has been effectively combined with online ESI-MS and atmospheric pressure chemical ionization (APCI)-MS for analyses of both lipid classes and molecular species (see below).

Conventional GC currently serves mainly for the separation and quantification of fatty acids as the methyl esters and sterols. Capillary columns, up to 100 m in length, coated with liquid phases of moderate polarity allow extensive but not complete resolution of all homologs and isomers. **Figure 2** shows a GC separation of a complex mixture of standard fatty acid methyl esters on a 100 m fused silica capillary column (SP-2560, Supelco). A temperature program from 140°C to 240°C permitted a separation of C4 to C24 saturated and polyunsaturated fatty acids. A total of 37 peaks were resolved and quantified by FID. Helium was used as a carrier gas. Presumably, further resolution and earlier elution would have been obtained with hydrogen as a carrier. However, many peaks remain unresolved in the 18:0 and 18:2 $n$ 6 region, including the methylene interrupted and noninterrupted 18:2 isomers. The picolinyl esters and dimethyloxazoline derivatives of unsaturated fatty acids have been used for a GC-MS determination of the location of the double bonds.

GC-MS and GLC are commonly used methods for the identification and quantification of sterols from samples of biological origin. **Figure 3** gives the retention times relative to 5 $\alpha$ -cholestane for the trimethylsilyl (TMS) ether derivatives of unsaturated C<sub>27</sub> sterols and related sterols on two 60 m capillary columns of moderate polarity. An inspection of the retention data indicates that both liquid phases fail to separate numerous sterols, even on highly efficient capillary columns. A preliminary resolution of the sterols into desmethyl, monomethyl, and dimethyl sterols is, therefore, required to provide supporting evidence for the identification of sterol structures. Careful attention to GC and MS conditions is necessary as is calibration of GC and MS data with authentic sterol standards. Furthermore, possible sterol decomposition under GC conditions, as well as the contribution of (Parent  $\pm$  2)<sup>+</sup> to the single ion mass chromatograms must also be kept in mind.

High-temperature GC on nonpolar capillary columns permits the resolution of such natural lipid esters as the mono- and diacylglycerols as the TMS ethers, and intact triacylglycerols and cholesteryl

**Figure 2** A gas-liquid chromatogram (with temperature programming from 140 to 240°C) of a complex mixture of standard fatty acid methyl esters separated on a 100-m fused silica capillary column (SP-2560, Supelco). Peak identification by carbon and double bond number: 1, 4:0; 2, 6:0; 3, 8:0; 4, 10:0; 5, 11:0; 6, 12:0; 7, 13:0; 8, 14:0; 9, 14:1; 10, 15:0; 11, 15:1; 12, 16:0; 13, 16:1; 14, 17:0; 15, 17:1; 16, 18:0; 17, 18:1n9c; 18, 18:1n9t; 19, 18:2n6c; 20, 18:2n6t; 21, 18:3n6; 22, 18:3n3; 23, 20:0; 24, 20:1n9; 25, 20:2; 26, 20:3n6; 27, 20:3n3; 28, 20:4n6; 29, 20:5n3; 30, 21:0; 31, 22:0; 32, 22:1n9; 33, 22:2; 34, 22:6n3; 35, 23:0; 36, 24:0; 37, 24:1n9. (Reproduced from *Chromatography* (2003/2004) Sigma-Aldrich Canada.)

esters based on carbon number, while high-temperature GC on capillary columns containing polarizable liquid phases allows the resolution of the above lipid classes on the basis of carbon number and degree of unsaturation. Both types of GC separations can be readily interfaced with online MS and MS/MS to provide unequivocal peak identification and quantification in relation to appropriate internal standards. High-temperature GC/FID may also be utilized for the analysis of molecular species of glycerophospholipids and sphingomyelins, provided the polar head groups are first removed by phospholipase C and the hydroxyl groups of the released diacylglycerols and ceramides are protected by silylation. Polar capillary GC/FID provides the highest resolution of the molecular species of glycerophospholipids via their diradylglycerol moieties along with superior quantification. **Figure 4** shows the polar capillary GC profiles of the diacylglycerol (A), alkylacylglycerol (B), and alkenylacylglycerol (C) moieties of plasma diradyl glycerophosphoethanolamines. Prior to GC, the diradylglycerols, as the TMS ethers, were resolved into the diacyl, alkylacyl, and alkenylacyl subclasses by normal phase HPLC. The major chromatographic peaks are identified in the figures by the most likely pairing of the fatty chains based on the retention times of the peaks. Recent work has demonstrated that the latter separations and quantification agree fully with the results of LC/ESI-MS analyses, which, however, are more rapid and more sensitive (see below).

At present, the chromatography of high molecular weight neutral lipids and polar lipids is usually performed by reversed phase HPLC, although a lack of a universal detector prevents the full utilization of this

analytical system. Light scattering detectors are not sufficiently sensitive, while manufacture of FIDs for HPLC applications has been discontinued. Online MS can provide the necessary detection capacity, but its high cost and variable response severely limits its general utilization. Reversed phase HPLC with ultraviolet (UV) detection is well suited for the analyses of molecular species of fatty acids, monoacylglycerols, and diacylglycerols, for which the derivatization step can be combined with the introduction of a UV absorbing or fluorescent ester or ether group, respectively. Thus, the pentafluorobenzoyl esters of fatty acids and pentafluorobenzyl ethers of acylglycerols have been well resolved and quantitatively measured by reversed phase HPLC/UV. Other UV absorbing or fluorescent fatty acid derivatives may be prepared for structural studies using HPLC-MS, as it is done using GC-MS.

Reversed phase HPLC with light scattering detection has been extensively utilized for the resolution of molecular species of triacylglycerols, where sufficiently large samples have been available. **Figure 5** shows a reversed phase HPLC separation of the complex molecular species of bovine milk fat triacylglycerols. A randomized sample of butterfat, the composition of which can be calculated on basis of random distribution of fatty acids, is used for determination of the component molecular species to serve as standard for identification of the naturally occurring triacylglycerol species.

Reversed phase HPLC has recently provided excellent resolution of reverse isomers within an enantiomeric diacylglycerol class. **Figure 6** demonstrates the reversed phase HPLC resolution as 3,5-dinitrophenylurethanes (3,5-DNPU) of standard

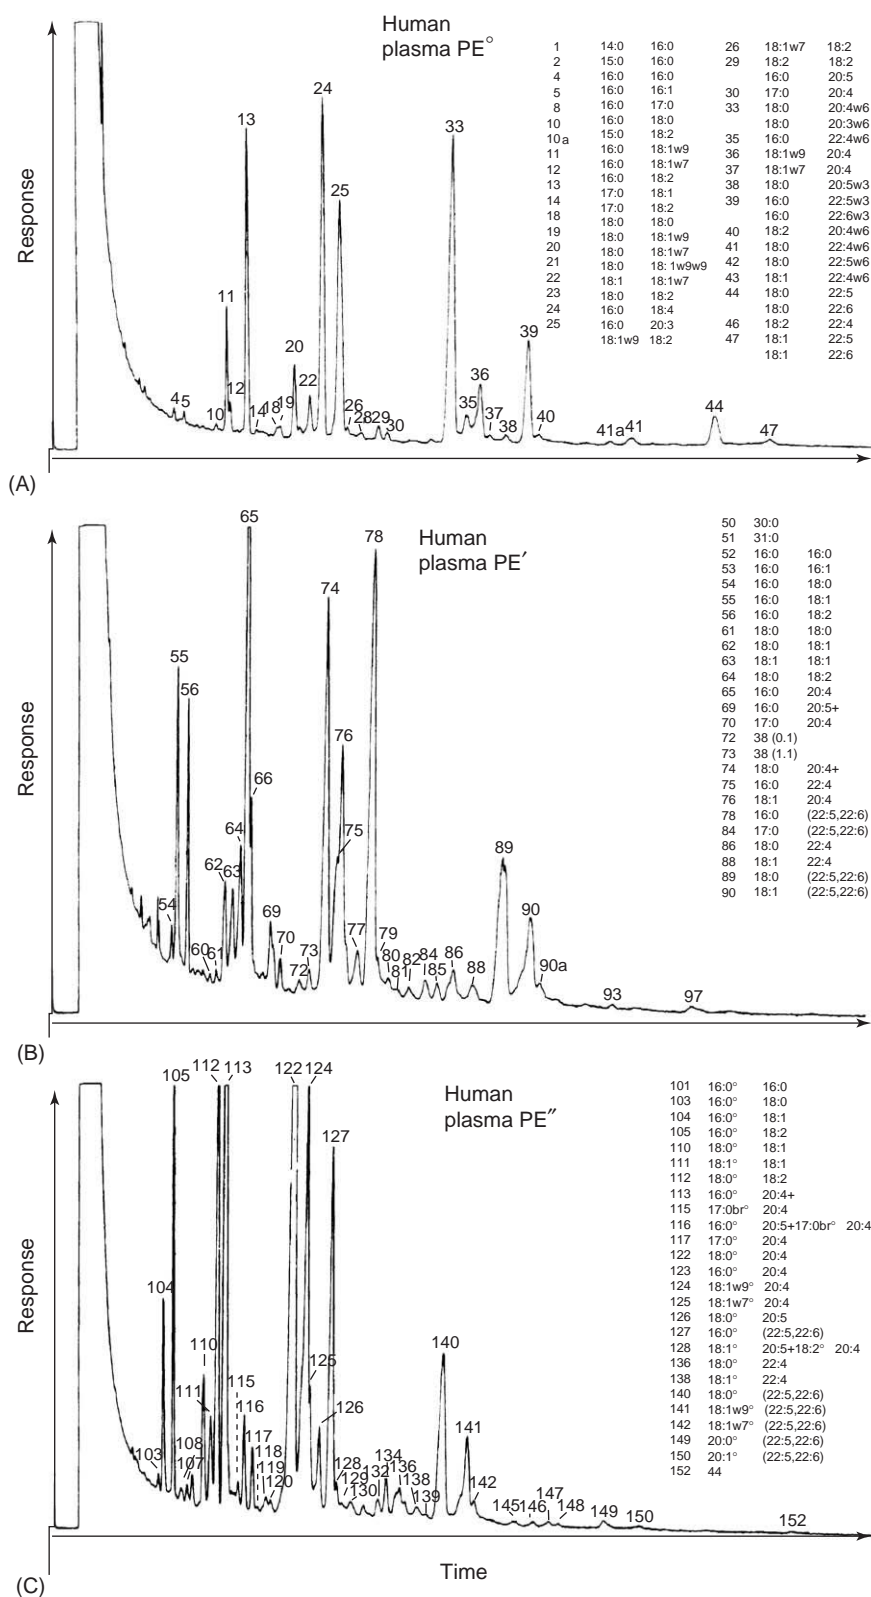

**Figure 3** Retention times relative to 5 $\alpha$ -cholestane for TMS ether derivatives of unsaturated C<sub>27</sub>-sterols and related sterols on DB-5 (60 m) and CP-Wax columns. Unsaturated sterols are all of 5 $\alpha$  configuration (or  $\Delta^4$  or  $\Delta^5$ ) and are designated by their unsaturation. (Reproduced with permission from Gerst *et al.* (1997) *Journal of Lipid Research* 38: 1685–1701.)

*rac*-1,2-diacylglycerols made up of a pair of reverse isomers, 1-palmitoyl-2-linolenoyl- and 1-linolenoyl-2-palmitoyl-*sn*-glycerols, as well as 1-palmitoyl-2-docosahexaenoyl- and 1-docosahexaenoyl-2-palmitoyl-*sn*-glycerols, and two other pairs of reverse isomers. These separations have been recently extended to the diacylglycerol moieties of naturally occurring glycerophospholipids in a search for the natural occurrence of the reverse isomers, which are conventionally determined by hydrolysis with phospholipase A<sub>2</sub>, which requires large amounts of sample, or MS, which is less accurate (see below).

Reversed phase HPLC has also been utilized for the resolution of molecular species of intact glycerophospholipids and sphingomyelins. Excellent resolutions have been obtained, but the monitoring of molecular species by UV of short wavelength has been unsatisfactory. Furthermore, the use of solvents including nonvolatile counterions has prohibited the interfacing of these chromatographic separations with online MS.

HPLC using chiral columns has proved well suited for the resolution of enantiomeric monoacylglycerols, monoalkylglycerols, monoalkenylglycerols, diacylglycerols, and alkylacylglycerols. The monoacylglycerols are resolved following the preparation of the di-dinitrophenylurethane derivatives, while the diacylglycerol separation is achieved with the mono-dinitrophenylurethanes. The racemates of even complex mixtures of diacylglycerols, such as those derived from fish oils, may be resolved into enantiomers without overlapping. The resolved enantiomers are identified and quantified by ESI-MS and the method has been widely applied in the analyses of the structure of natural fat and oils following partial Grignard deacylation. **Figure 7** shows the chiral phase HPLC separation of the enantiomeric *sn*-1,2- and *sn*-2,3-diacylglycerols derived from manhaden oil. The most unsaturated *sn*-1,2-diacylglycerols are eluted well ahead of the most saturated of *sn*-2,3-diacylglycerols. The X-1,3-diacylglycerols overlap with the *sn*-1,2-diacylglycerols, unless they have been first resolved by TLC or HPLC using borate-treated adsorbents. Using a chiral column of opposite configuration HPLC results in a reverse order of elution of the enantiomers, which may be taken advantage of in those instances where the tail end of the *sn*-1,2-enantiomers overlaps in part with the leading edge of the *sn*-2,3-enantiomers. The composition of the molecular species is best deduced from the fatty acid pairing seen by online LC/ESI-MS.

Chiral phase HPLC can also provide a resolution of the reverse isomers within an enantiomeric diacylglycerol. Thus, under appropriate elution conditions, full baseline resolution may be obtained between pairs of enantiomeric diacylglycerols, such as 1-docosahexaenoyl-2-palmitoyl- and 1-palmitoyl-2-docosahexaenoyl-*sn*-glycerols, which are present among the diacylglycerols derived from fish oils, leading to confusion during mass spectrometric identification of the molecular species of enantiomeric diacylglycerols resolved by chiral phase HPLC. **Figure 8** shows the chiral phase HPLC resolution of the reverse isomers and enantiomers of 1,2-diacyl-*rac*-glycerols containing polyunsaturated acyl chains as the 3,5-DNPs on (*R*)-1-(1-naphthyl)ethylamine

**Figure 4** Polar capillary GC profiles of the diradylglycerol moieties of human plasma glycerophosphoethanolamines: (A) diacylglycerols; (B) alkylacylglycerols; (C) alkenylacylglycerols. Peak identifications are given in the figures. GC conditions: columns, 15 m  $\times$  0.32 mm fused silica capillary coated with cross-bonded RTx 2330; carrier gas, H<sub>2</sub>, 3 psi; temperature, 250°C, isothermal. Sample: 1  $\mu$ l of 0.1% diradylglycerol TMS ethers in hexane. (Reproduced with permission from Myher JJ, Kuksis A, and Pind S (1989) Molecular species of glycerophospholipids and sphingomyelins of human plasma: comparison to red blood cells. *Lipids* 24: 408–418.)

**Figure 5** Reversed phase HPLC (linear gradient of 10–90% isopropanol in acetonitrile at 25°C) of natural (top) and rearranged (bottom) butterfat triacylglycerols as obtained with light-scattering detector. Peak identification by carbon and double bond number. (Reproduced with permission from Marai L, Kuksis A, and Myher JJ (1994) Reversed-phase liquid chromatography–mass spectrometry of the uncommon triacylglycerol structures generated by randomization of butteroil. *Journal of Chromatography A* 672: 87–99.)

liquid phase. There is reasonably good resolution of the reverse isomers of 1-docosahexaenoyl-2-palmitoyl-*rac*-glycerol (22:6–16:0), 1-docosahexaenoyl-2-oleoyl-*rac*-glycerol (22:6/18:1), and 1-eicosapentaenoyl-2-oleoyl-*rac*-glycerol (20:5/18:1) only within their *sn*-2,3-enantiomers, for which the isomers with the acyl group of the higher degree of unsaturation are in the secondary position. There was a similar resolution of the reverse isomers within *sn*-1,2-enantiomers on the chiral stationary phase having the opposite configuration. Again the reverse isomers

with the acyl groups of higher degree of unsaturation in the secondary position were retained more strongly. The presence of long chains of saturated or monounsaturated fatty acids in the secondary position, which are close to 3,5-DNPU group, apparently interfered with diastereomeric hydrogen-bonding and pi-pi donor-acceptor interaction between the 3,5-DNPU and (*R*)- or (*S*)-1-(1-naphthyl)ethylamine stationary phases and resulted in impaired separation of diacylglycerols having long acyl chains in the secondary position.

**Figure 6** Reversed phase HPLC resolution (isocratic acetonitrile at 18°C.) of the reverse isomers of 1,2-diacyl-*rac*-glycerols containing polyunsaturated acyl chains as 3,5-dinitrophenylurethanes. Peak identification: A, 1-linolenoyl-2-palmitoyl-*rac*-glycerol and 1-palmitoyl-2-linolenoyl-*rac*-glycerol; B, 1-docosahexaenoyl-2-palmitoyl-*rac*-glycerol and 1-palmitoyl-2-docosahexaenoyl-*rac*-glycerol; C, 1-linolenoyl-2-oleoyl-*rac*-glycerol and 1-oleoyl-2-linolenoyl-*rac*-glycerol; D, 1-arachidonoyl-2-oleoyl-*rac*-glycerol and 1-oleoyl-2-arachidonoyl-*rac*-glycerol; E, 1-eicosapentaenoyl-2-oleoyl-*rac*-glycerol and 1-oleoyl-2-eicosapentaenoyl-*rac*-glycerol; F, 1-docosahexaenoyl-2-oleoyl-*rac*-glycerol and 1-oleoyl-2-docosahexaenoyl-*rac*-glycerol. (Reproduced with permission from Itabashi Y, Myher JJ, and Kuksis A (2000) High performance liquid chromatographic resolution of reverse isomers of 1,2-diacyl-*rac*-glycerols as 3,5-dinitrophenylurethanes. *Journal of Chromatography A* 893: 261–279.)

An effective resolution of *rac*-diacylglycerols may be obtained by normal phase HPLC following preparation of the diastereomeric dinitrophenylethylurethanes. In this instance the *R* and *S* derivatives may be prepared, which results in opposite elution order of the diastereomers. Again, online ESI-MS is necessary for identification of the molecular species as the elution order of the molecules is complicated by both adsorption and partition effects. Normal phase HPLC on a silver-loaded cation-exchange column has permitted resolution of the reverse isomers of *rac*-diacylglycerols as the 3,5-DNPU, such as

1-palmitoyl-2-oleoyl-*rac*-glycerol and 1-oleoyl-2-palmitoyl-*rac*-glycerol, as well as other pairs of reverse isomers containing fatty chains of greater differences in their length or unsaturation. The separation of chiral compounds by packed column SFC has been a great success for the pharmaceutical industry. Almost all of the chiral selectors used in gas and liquid chromatography have been successfully applied in SFC.

Normal phase and to a lesser extent reversed and chiral phase HPLC have been combined online with thermospray ionization (TSI)-MS, ESI-MS, or APCI-MS for the purpose of identification and

**Figure 7** Chiral phase ((*R*)-(+)-1-(1-naphthyl)ethylamine polymer) HPLC resolution of the diacylglycerol moieties of menhaden oil triacylglycerols, as dinitrophenylurethanes. (A) X-1,3-diacylglycerols; (B) *sn*-1,2(2,3)-diacylglycerols. Peak identification confirmed by LC/NCI-MS as equivalent carbon numbers: 1, 32; 2, 30; 3, 28; 4, 26; 5, 24; 6, 22; 7, 20. Peaks monitored at 254 nm during isocratic elution with hexane–1,2-dichloroethane–ethanol (40:10:1, by vol). (Reproduced with permission from Itabashi Y, Kuksis A, Marai L, and Takagi T (1990) HPLC resolution of diacylglycerol moieties of natural triacylglycerols on a chiral phase consisting of bonded (*R*)-(+)-1-(1-naphthyl)ethylamine. *Journal of Lipid Research* 31: 1711–1717.)

quantification of lipid classes and molecular species. The success has depended on the lipid class involved and the exact methodology applied. Because of the ease of interfacing of the above methodologies, online TSI-MS, ESI-MS, and APCI-MS have been utilized most often. Online ESI-MS has given excellent results with both neutral and polar lipids, while APCI-MS has given best results when applied to triacylglycerols. In the case of packed column SFC, a combination with time-of-flight MS has been especially successful, although other MS methods have also been coupled to it.

The choline-containing phospholipids (PtdCho, lysoPtdCho, and sphingomyelin) are commonly detected by ESI-MS in the positive ion mode although in the negative ion mode they may show higher response as the chloride adducts. In the negative ion mode, PtdCho may be determined also as the

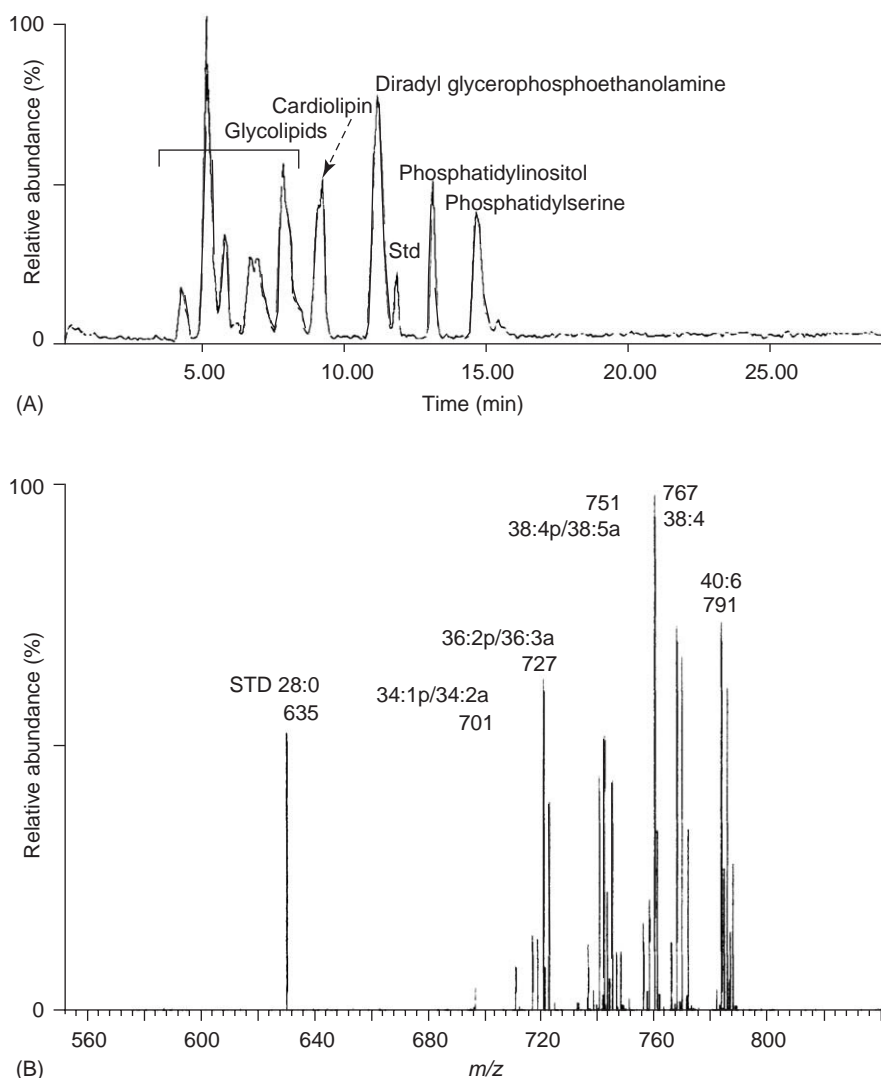

$[M - 15]^-$  ion resulting from the loss of a methyl ( $-\text{CH}_3$ ) group from the choline moiety at cone ionization voltages somewhat higher than those necessary for the ionization of the acidic glycerophospholipids. The individual molecular species making up the various choline-containing peaks may be readily extracted from the total ion current profiles and quantified in relation to an appropriate internal standard for each phospholipid class. The serine, inositol, and ethanolamine glycerophospholipids are commonly determined in the negative ion mode, although the ethanolamine phospholipids also give strong signal in the positive ion mode. In both instances the prior HPLC resolution of the lipid classes, including partial resolution of isobaric molecular species, serves to facilitate the subsequent identification of the molecular species based on the molecular ion and the fragment ion spectra. The interpretation of the mass spectra of the glycerophospholipids is greatly facilitated by the development of a software algorithm for automatic interpretation of the mass spectra. The algorithm interprets spectra according to user-specified identification of ions, corrects the ion intensities for abundances of naturally occurring isotopes, applies response correction factors to each identified ion, quantifies the identified compounds relative to an internal standard, and applies sample dilution factors to obtain quantitative results. **Figure 9** shows the LC/ESI-MS analysis of glycerophospholipids in a total lipid extract of guinea pig brain. The total ion chromatogram recorded in negative ionization mode shows the separation of the phospholipid classes (A). The mass spectrum averaged over the diacylglycerophosphoethanolamine peak displaying  $[M - H]^-$  ions of molecular species along with the identification of the major species is also shown (B). In the interpretation process the algorithm searches the input spectrum against the user-defined auxiliary file and accepts all identifications in which the measured  $m/z$  value fulfills the criteria ( $m/z \pm \text{range}$ ). The allowed error in measurement of  $m/z$  values of  $[M - H]^-$  or  $[M + H]^+$  ions must be less than 0.5 Th. The compound identification process results in a list of identified compounds, their measured  $m/z$  values, and abundances (**Table 1**). Automatic processing of the spectra was shown to be accurate and reliable by testing with spectra of glycerophospholipids obtained by LC/ESI-MS with manual interpretation of the spectra.

At present many laboratories have abandoned LC-MS in favor of MS/MS or MS/MS/MS as a method of determining molecular species of phospholipids. Total lipid extracts are subjected to MS analysis for molecular ions, from which fragment ions are obtained by collision-induced dissociation (CID) for

**Figure 8** Chiral phase HPLC resolution of the reverse isomers and enantiomers of 1,2-diacyl-*rac*-glycerols containing polyunsaturated acyl chains as 3,5-dinitrophenylurethanes on (*R*)-1-(1-naphthyl)ethylamine. Peak identification (from left to right) A, 1-linolenoyl-2-palmitoyl + 1-palmitoyl-2-linolenoyl-*sn*-glycerols and 2-palmitoyl-3-linolenoyl + 2-linolenoyl-3-palmitoyl-*sn*-glycerols; B, 1-docosahexaenoyl-2-palmitoyl + 1-palmitoyl-2-docosahexaenoyl-*sn*-glycerols and 2-palmitoyl-3-docosahexaenoyl + 2-docosahexaenoyl-3-palmitoyl-*sn*-glycerols; C, 1-eicosapentaenoyl-2-oleoyl + 1-oleoyl-2 eicosapentaenoyl-*sn*-glycerols and 2-oleoyl-3-eicosapentaenoyl + 2-eicosapentaenoyl-3-oleoyl-*sn*-glycerols; D, 1-docosahexaenoyl-2-oleoyl + 1-oleoyl-2-docosahexaenoyl-*sn*-glycerols and 2-oleoyl-3-docosahexaenoyl + 2-docosahexaenoyl-3-oleoyl-*sn*-glycerols. A mixture of the reverse isomers of 1,2-diacyl-*rac*-glycerols was analyzed separately. HPLC conditions as in **Figure 6**. analyses. When high-quality chromatography results have been compared to modern MS/MS analyses, closely similar results have been obtained. Table 2 demonstrates that the composition of molecular species of plasma PtdIns obtained by polar capillary GC matches closely that obtained by normal phase LC/ESI-MS. Similar close agreement has been realized between the GC analyses of the molecular species of the diradylglycerols derived from plasma choline and ethanolamine phospholipids and the molecular species of these phospholipids derived from normal phase LC/ESI-MS analyses. There was no evidence that the preliminary isolation of the phospholipid classes by TLC and subsequent subfractionation of

the diradylglycerol subclasses by normal phase HPLC would have resulted in significant losses of the polyunsaturated species. The MS/MS analyses suffer from inability to cope adequately with the identification of isobaric species and the sodium adducts (positive ion mode), the masses of which can be mistaken for molecular species having two additional methylene units and two double bonds. The MS/MS assays are also unable to cope effectively with the quantification of reverse isomers and are not at all able to distinguish between enantiomers. Nevertheless, the high speed of MS/MS analyses and minimal sample requirements provide a definite advantage for studies in lipidomics (see below).

**Table 1** An example of a single input file generated by the interpretation as a result of processing the molecular mass distribution spectrum of a diradylglycerophosphoethanolamine

Identifications of  $[M - H]^-$  ions of molecular species are given according to the selected  $m/z$  range. Data in range  $m/z$  745–780 are shown. Molecular species are identified by number of acyl carbons:number of double bonds. p, alkenylacyl; a, alkylacyl; #, disabled. (Reproduced with permission from Kurvinen J-P, Aaltonen J, Kuksis A, and Kallio H (2002) Software algorithm for automatic interpretation of mass spectra of glycerolipids. *Rapid Communications in Mass Spectrometry* 16: 1812–1820.)

Both LC–MS and MS/MS have permitted greatly improved analyses of various lipid oxidation products in the form of the intact neutral and polar lipid molecules or their partial degradation products, which was not possible by chromatographic methods alone. Thus, the hydroperoxides, epoxides, hydroxides, isoprostanes, and the core aldehydes and acids generated during nonenzymatic peroxidation have been identified in plasma lipoproteins and atheroma samples and have provided a new basis for hypotheses about the origin and progression of vascular disease.

Current LC–MS or MS/MS, however, has not been found adequate for the analysis of the polyphosphates of PtdIns, although PtdIns itself has been readily analyzed (see above). This is due to the extremely low concentrations in tissue and cell extracts of the PtdIns polyphosphates, which must be detected in their radioactive form. This can be best done by radio-chromatography on anion-exchange HPLC columns with standards serving as chromatographic carriers.

Nuclear magnetic resonance (NMR) spectroscopy is a powerful, nonselective, and nondestructive technique that provides an alternative method for analysis of components in complex mixtures of lipids. Specifically, lipophilic compounds may be determined either by  $^1\text{H}$  NMR, which offers high sensitivity but limited resolution, or by  $^{13}\text{C}$  NMR, which enables a much more detailed analysis of various lipids owing to its higher resolution, but suffers from the drawback of the low natural abundance of the isotope. Recently, the sensitivity of localized  $^{13}\text{C}$  NMR has been improved up to fivefold by applying proton decoupling and nuclear Overhauser enhancement in experiments on human tissues. Thus, lipid extracts of liver tissue have been analyzed by  $^{13}\text{C}$  and  $^1\text{H}$  NMR at 9.4 T. The spectra allowed the measurement of the free fatty acid to total fatty acid chain ratio, the polyunsaturated to monounsaturated lipid ratio, the glycerophospholipid to triacylglycerol ratio, the total cholesterol to total fatty acid molar ratio, the acylcholesterol to cholesterol ratio, the PtdCho to PtdEtn molar ratio, and the unsaturation

ratio of the fatty acid chains. Other methods, such as infrared, Fourier transform infrared, and optical rotation have also provided critical data for the identification and quantification of specific lipid classes and molecular species but have been employed to a limited extent only because of lack of general applicability.

## Emerging Techniques

The lipid analyses for the immediate future require increased speed of analysis and automated data processing. The demands of lipidomics and studies on lipid metabolome are such that they can be met only by hundreds or even thousands of parallel analyses of minute samples. This requirement is clearly beyond the capability of the current instrumentation and methodology, although some progress has already been made. Multiparallel analyses of mRNA and proteins are central to present day functional genomics initiatives. Metabolite profiling is a new tool for a comparative display of gene function, as it has the potential to provide deeper insight into complex regulatory processes as well as to determine the phenotype directly. Recently, GC–MS has been used to quantify over 300 distinct compounds from *Arabidopsis thaliana* leaf extracts. Comparisons of four *Arabidopsis* genotypes (two homozygous ecotypes and a mutant of each ecotype) showed that each

genotype possesses a distinct metabolic profile. Others have demonstrated that quantification of the change of several metabolite concentrations relative to the concentration change of one selected metabolite can reveal the site of action, in a metabolic network, of a silent gene. A similar approach to analysis of phenotype of silent mutations in yeast has been attempted by LC/ESI-MS of the molecular species of the major glycerophospholipids. Another approach to an assessment of the lipid metabolome (the concentration of each lipid class and each of its constituent fatty acids) has been taken by a combination of TLC resolution of the lipid classes followed by capillary GC of the fatty acids. Application of the method to evaluate the effect of chronic feeding of a low dose of rosiglitazone on lipid metabolism of diabetic F1 males revealed key targets of the action of the drug on lipid metabolism. It may be recalled that only a slightly less sophisticated approach to lipid profiling was described in 1966, where a packed GC column was used for the fatty acid analyses of the lipid classes resolved by TLC. Since repeated attempts to integrate TLC with MS/MS have been unsuccessful, a substitution of normal phase HPLC for the TLC step would appear to be clearly in order. This would allow integration with MS and analyses of the component fatty acids in the form of the molecular species of the various lipid esters. Except for the LC/ESI-MS analyses of the yeast metabolome, the above analyses do not include determination of

molecular species, which provide the basis of the lipid–protein interaction and metabolic function of glycerolipids. Clearly, future analyses of the lipid metabolome of any biological system will require analyses of molecular species, which may very well be provided by instant MS/MS or MS/MS/MS analyses with computerized data assessment that would yield quantitative estimates of the various lipid classes, the component molecular species, and detailed fatty acid composition. Furthermore, the determination of the molecular species of the neutral glycerolipids, in the future, will require the quantification of the reverse isomers as well as the enantiomers. Thus, triacylglycerols in lipid-rich lipoproteins could have come from the meal itself, could have been re-esterified in the intestine, or could have arisen from *de novo* synthesis in the liver. Only chiral chromatography of enantiomeric diacylglycerols has been able to distinguish among these triacylglycerol species. It is hoped that automated radio-chromatographic systems will be developed for the profiling of the PtdIns polyphosphates, which serve as lipid messengers, protein receptors, and membrane anchors.

## Trivial Names and Systematic Nomenclature

Fatty acids are known by several names: volatile fatty acids from  $\text{C}_1$  to  $\text{C}_5$ , fatty acids from  $\text{C}_6$  to  $\text{C}_{24}$ , long-chain fatty acids from  $\text{C}_{25}$  to  $\text{C}_{40}$ , and very long chain fatty acids above  $\text{C}_{40}$ . One can also find other names in the chemical nomenclature. The correct name for this group of carboxylic aliphatic acids (with or without any additional functions) is simply,

fatty acids. It is possible to find trivial, Liege, and Geneva nomenclatures remaining in modern texts, despite the acceptance of the IUPAC nomenclature in 1957. Fatty acids are carboxylic aliphatic acids with the general formula,  $\text{H}(\text{CH}_2)_n\text{COOH}$ . Aliphatic fatty acids are named by dropping the final ‘e’ from the parent alkane, and then adding the term ‘-oic acid’ to the root. The nomenclature for any additional functions on the principal chain follows the rules of the IUPAC convention of 1957. The first members in the homologous series are usually named using their trivial names (Figure 1).

Fatty acids can have different chemical functional groups substituting for H- in the aliphatic principal chain, leading to different classes of fatty acids.

molecular species, which provide the basis of the lipid–protein interaction and metabolic function of glycerolipids. ## The Discovery and History of Use of Fatty Acids and Their Distribution in Nature

A narration on the use of fatty acids is contained in ancient historical texts, such as those on the history of the war of Rome with Hannibal in about 200 BC. The Phoenicians made soap by heating animal fat or vegetable oil with wood ash more than 2000 years ago. The alkali salts of fatty acids obtained from the hydrolysis of fats and oils are known as soaps.

Formic acid was first described by S. Fisher in 1670, who obtained it from the distillate of ants. The first nine members of the aliphatic carboxylic acids homologous series are liquids at room temperature. The first solid aliphatic carboxylic acid is decanoic acid, which has a melting point of 31.5°C. An unsaturated principal chain considerably lowers the melting point temperature. For example, *cis*-oleic acid is a liquid at 5°C, and the *cis* and *trans* isomers have notably different melting temperatures. The *trans* isomer of oleic acid is eladic acid, which has a melting point of 44–45°C. The first three members of the aliphatic carboxylic acid homologous series are easily soluble in water.

Fatty acids exist in nature as pure free fatty acids (FFAs), or as part of more complex molecules, known as lipids. Those fatty acids that are covalently bonded to proteins, alcohols, sugars, or other organic molecules are termed ‘bound fatty acids’ (BFAs). There are also a number of synthetic molecules that can be classified as substituted fatty acids or synthetic fatty acids (SFAs), such as 2-(*p*-chlorophenoxy)-2-methylpropionic acid.

Formic acid, a C<sub>1</sub> fatty acid, is found in ants, and acetic acid, a C<sub>2</sub> fatty acid, is found in some scorpions and plants, such as in stinging nettle. The C<sub>4</sub>–C<sub>16</sub> fatty acids are found in different fats and oils. Pelargonic acid, C<sub>9</sub>H<sub>18</sub>O<sub>2</sub>, is part of an ester found in the plant, pelargonium. Capric acid, C<sub>10</sub>H<sub>20</sub>O<sub>2</sub>, was hydrolyzed from *Cuphea llavea* Llave et Lex, and *Lythaceae* seed oil. *Myristicaceae* are known to contain myristic acid. Behenic, lignoceric, and

hexacosanoic acids are usually components of animal and human serum. Most of the natural FAs have an odd number of carbon atoms in their chain, while some natural fatty acids and SFAs may have an even number of carbon atoms in their chain. Branched fatty acids are common in microorganisms, and they can be found with between one and upwards of 20 carbon atoms in their branches.

Branched fatty acids exist as either *iso*-acids or *anteiso*-acids, where the number of branches can vary from one (monobranched) to many (multibranched). There are a number of functional groups that may be present in the principal aliphatic chain of fatty acids, such as hydroxyl-, epoxy-, keto-, fluoride (e.g.,  $\omega$ -fluoro- $\Delta^9$ -octadecanoic acid), chloride, bromide, and iodine, and as sulfur (e.g., in tetradecylthioacetic acid), cyclopropane and cyclopropene rings, and monoenoic, polyenoic, or acetylenic (triple) bonds, and cyclopentane rings (e.g., in prostaglandin E<sub>1</sub>). Other functional groups that may be present include cyclopentene rings (e.g., in chaulmoogric acid), furanoid rings (e.g., in furanoid acid F<sub>6</sub>), and cyclohexene rings (e.g., in  $\alpha$ -retinoic acid). Two more groups are phenyl rings in some synthetic pesticides (e.g., in  $\alpha$ -(2,4,5-trichlorophenoxy)propionic acid, or in the drug ibuprofen ( $\alpha$ -methyl-4-(2-methylpropyl)benzeneacetic acid), and naphthyl rings as in the drug naproxen ([S]-6-methoxymethyl-2-naphthaleneacetic acid). Fatty acids may have unsaturation in chains or in rings. The character of the unsaturated chains can be single, non-conjugated polyunsaturated bonds, conjugated polyunsaturated bonds, or polyunsaturated with cumulative bonds. The unsaturated fatty acids can be in either the *trans* or *cis* configuration.

## Normal Saturated Fatty Acids

Aliphatic fatty acids have the general formula, H(CH<sub>2</sub>)<sub>*n*</sub>COOH, where *n* ranges from 0 to over 40 (Table 1).

## Monobranched Saturated Fatty Acids

Monobranched *iso*-fatty acids have the general formula, (CH<sub>3</sub>)<sub>2</sub>CH(CH<sub>2</sub>)<sub>*n*</sub>COOH (Table 2); the *anteiso*-fatty acids have the general formula, CH<sub>3</sub>CH<sub>2</sub>CHCH<sub>3</sub>(CH<sub>2</sub>)<sub>*n*</sub>COOH; and in addition, there are branched *anteiso*-fatty acids with branches occurring in the middle of the principal chain, which have the general formula, CH<sub>3</sub>(CH<sub>2</sub>)<sub>*n*</sub>CHCH<sub>3</sub>(CH<sub>2</sub>)<sub>*m*</sub>COOH. In nature, the D-form is the dominant form.

## Multibranched Saturated Fatty Acids

Multibranched saturated fatty acids can have the following configurations:  $R-(CH_2CHCH_3CH_2CH_2)_n-CH_2CHCH_3CH_2COOH$  (where  $R=H$  and  $n=2$  for farnesic acid) or  $R-(CH_2CHCH_3CH_2CH_2)_n-COOH$  (where  $R=H$  and  $n=3$  for 2,8,12-TMTD), or  $R-(CH_2CHCH_3CH_2CH_2)_n-CH_2CHCH_3COOH$  (where  $R=H$  and  $n=3$  for pristanic acid) (Figure 2), and  $R-(CH_2CHCH_3CH_2CH_2)_n-CH_2CHCH_3CH_2COOH$  (where  $R=H$  and  $n=3$  for phytanic acid).

The common carbon sequence in all these molecules has the  $(CH_2CHCH_3CH_2CH_2)$  architecture. Mycrocercosic acid has the formula  $C_{32}H_{64}O_2$  (2,4,6,8-tetramethyloctacosanoic acid) and has four branches in the principal chain. Branched fatty acids (the mycolic acids) are found in bacteria belonging to the *Mycobacterium-Nocardia-Corynebacterium* group. They have often other functional groups in their chain, and should formally belong to the multifunctional fatty acids.

## Saturated Monocarboxylic Fatty Acids with a Cyclohexane or Cycloheptane Ring

Some saturated FAs have a ring system connected to the chain, such as 11-cyclohexylundecanoic acid, 13-cyclohexyltridecanoic acid, and cycloheptaneundecanoic acid (Figure 3).

**Figure 2** Pristanic acid, or 2,6,10,14-tetramethylpentadecanoic acid.

**Figure 3** Monocarboxylic acids with a cyclohexane or cycloheptane ring.

## Partially Unsaturated Multibranched Fatty Acids

This class of fatty acids has the general formula of  $R-(CH_2CH-CH_3CH_2CH_2)_n-CH-C=CH-COOH$ , where  $R=H$ . These saturated and partially unsaturated multibranched fatty acids belong to the isoprenoid acid family, and in nature, isoprenoid acids are often found in microorganisms and plants. Phytanic acid, whose systematic name is 3,7,11,15-tetramethyl-2-hexadecenoic acid (Figure 4), is one member of this class.

## Cyclopropane and Cyclopropene Fatty Acids

The general formula for fatty acids with a cyclopropane ring is

The homologous series with  $n=5$  and  $m=7$  includes *cis*-9,10-methylenehexadecanoic acid and the homologous series with  $n=5$  and  $m=9$  includes lactobacillic acid (*cis*-11,12-methyleneoctadecanoic acid). The homologous series with  $n=7$  and  $m=6$  includes dihydromalvalic acid (systematic name is 2-octyl-cyclopropaneheptanoic acid) (Figure 5) and the homologous series with  $n=7$  and  $m=7$  includes dihydrosterculic acid (systematic name is *cis*-9,10-methyleneoctadecanoic acid).

Fatty acids with a cyclopropene ring have the general formula,

Malvalic acid (systematic name is 2-octyl-1-cyclopropene-1-heptanoic acid) has  $n=7$  and  $m=6$

**Figure 4** Phytanic acid, or 3,7,11,15-tetramethyl-2-hexadecenoic acid.

**Figure 5** Dihydromalvalic acid or 2-octyl-cyclopropaneheptanoic acid.

(Figure 6), while sterculic acid (systematic name is *cis*-9,10-methyleneoctadec-9-enoic acid) has  $n=7$  and  $m=7$ .

## Cyclopentene Fatty Acids

Some of the fatty acids have the general formula,  $R-CH_2(CH_2)_nCOOH$ , where R is a cyclopentene ring. Examples are, alepric acid ( $C_{14}H_{24}O_2$ ), hydrocarpic acid ( $C_{16}H_{28}O_2$ ), and chaulmoogric acid ( $C_{18}H_{32}O_2$ ). Gorlic acid (systematic name is 13-(2-cyclopenten-1-yl)-6-tridecenoic acid) (Figure 7) has an unsaturation in principal chain, with the general formula  $R-(CH_2)_6CH=CH(CH_2)_4COOH$ , where R is a cyclopentene ring.

## Normal Monounsaturated Fatty Acids

The family of monounsaturated fatty acids (Table 3) with one double bond (general formula  $CH_3(CH_2)_nCH=CH(CH_2)_mCOOH$ ), may exist as

**Figure 6** Malvalic acid or 2-octyl-1-cyclopropene-1-heptanoic acid.

**Figure 7** Gorlic acid or 13-(2-cyclopenten-1-yl)-6-tridecenoic acid.

*trans*-isomers, but in nature, the *cis*-isomers predominate.

Some of the monounsaturated fatty acids may also have branched chains, as does, for example, 3-methylcrotonic acid (systematic name is 2-butenic acid) (Figure 8).

## Polyunsaturated Fatty Acids with and without a Cyclohexene Ring

The polyunsaturated fatty acids family is widely distributed throughout nature. They have several double bonds in the principal chain. Common dienic acids are *cis*-,*cis*-9,12-octadecadienoic acid (linoleic acid), *trans*-,*trans*-9,12-octadecadienoic acid (linoleic acid), 5,9-heneicosadienoic acid, 5,9-docosadienoic acid, and 5,9-tricosadienoic acid.

The common trienoic fatty acids are *cis*-,*cis*-,*cis*-9,12,15-octadecatrienoic acid ( $\alpha$ -linolenic acid), *cis*-,*cis*-,*cis*-6,9,12-octadecatrienoic acid ( $\gamma$ -linolenic acid), *cis*-,*cis*-,*cis*-8,11,14-icosatrienoic acid (dihomo- $\gamma$ -linolenic acid), 5,9,13-eicosatrienoic acid, and 5,9,13-docosatrienoic acid. An example of a tetraenoic fatty acid is *cis*-,*cis*-,*cis*-,*cis*-5,8,11,14-icosatetraenoic acid (arachidonic acid). The discovery of new polyunsaturated acids is an ongoing process, with the recent discovery of 5,9-heneicosadienoic acid, 5,9-docosadienoic acid, 5,9-tricosadienoic acid, trienoic 5,9,13-eicosatrienoic acid, and 5,9,13-docosatrienoic acid from *Stoichactis helianthus*. Geranoic acid (systematic name is 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraenoic acid) (Figure 9), nerolic and farnesoic acids are polyunsaturated fatty acids with branches in their structures.

**Figure 8** Monounsaturated fatty acids.

**Figure 9** Geranoic acid or 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraenoic acid.

The principal chain and the ring can both be unsaturated, as is found in  $\alpha$ -retinoic and  $\beta$ -retinoic acids. The systematic name of  $\beta$ -retinoic acid is (all-*E*)-3,7-dimethyl-9-(2,6,6-trimethyl-1-cyclohexen-1-yl)-2,4,6,8-nonatetraenoic acid) (Figure 10). It has four double bonds in the principal chain and one in the cyclohexene ring.

## Acetylenic Fatty Acids

Triple bonds are often found in fatty acids of plant origin. Fatty acids, such as stearolic 9-octadecynoic (Figure 11), behenolic 13-docosynoic, and clupanodonic 4,7,11-docosatrien-18-ynoic acids have a triple bond in their chains. Clupanodonic acid has three double bonds and an acetylenic bond.

## Hydroxy Fatty Acids

Hydroxy fatty acids (HFAs) (Table 4) have hydroxyl functional groups attached to the principal chain, and they can be both saturated and unsaturated. The principal chain can be branched, and these branches are sometimes quite long.

The main positions of attachment of the hydroxyl to the chain are the  $\alpha$ -attachment to the  $C_2$  site, and the  $\beta$ -attachment to the  $C_3$  site. The general formula

for  $\alpha$ -hydroxy fatty acids is  $\text{CH}_3(\text{CH}_2)_n\text{CH}(\text{OH})\text{COOH}$ , while the  $\beta$ -hydroxy fatty acids have the general formula of  $\text{CH}_3(\text{CH}_2)_n\text{CH}(\text{OH})\text{CH}_2\text{COOH}$ .

There are two other HFA homologous series: the  $\omega$ - and  $(\omega - 1)$ . The general formula for  $\omega$ -hydroxy fatty acids is  $\text{HOCH}_2(\text{CH}_2)_n\text{COOH}$ ; and the general formula for  $(\omega - 1)$  HFAs is  $\text{CH}_3\text{CH}(\text{OH})(\text{CH}_2)_n\text{COOH}$ . Other functions, such as branches or double bonds, are often found in HFAs, for example, in 3-hydroxy-13-methyltetradecanoic and 3-hydroxy-15-methylhexadecanoic acids. An unsaturated hydroxy fatty acid is ricinoleic acid (12-hydroxy-*cis*-9-octadecenoic acid).

Two or more hydroxy functions can be present in the principal chain, for example, in 9,10-dihydroxyoctadecanoic acid and in ustilic acid (2,15,16-trihydroxyhexadecanoic acid) (Figure 12).

Some of bacterial cell walls and bacterial lipopolysaccharides both contain  $\beta$ -hydroxy branched and unbranched fatty acids.

## Fatty Acids with a Keto Function

The homologous series of keto fatty acids (KFAs) are made up from the  $\alpha$ -,  $\beta$ -, and  $(\omega - 1)$  KFAs. The  $\alpha$ -KFAs have the general formula  $\text{CH}_3(\text{CH}_2)_n\text{COCOOH}$ ; the  $\beta$ -KFAs  $\text{CH}_3(\text{CH}_2)_n\text{COCH}_2\text{COOH}$ ; and the  $(\omega - 1)$  KFAs  $\text{CH}_3\text{CO}(\text{CH}_2)_n\text{COOH}$ .

**Figure 10**  $\beta$ -Retinoic acid or (all-*E*)-3,7-dimethyl-9-(2,6,6-trimethyl-1-cyclohexen-1-yl)-2,4,6,8-nonatetraenoic acid.

**Figure 11** Stearolic acid or 9-octadecynoic acid.

## Prostaglandins, Prostacyclin, and Thromboxanes

The prostaglandins, prostacyclin, and the thromboxanes are prostanoids, and from a chemical perspective, the prostanoids are fatty acids. The

**Figure 12** Ustilic acid or 2,15,16-trihydroxyhexadecanoic acid.

**Table 4** Some of the hydroxy fatty acids

Systematic name	Trivial name	Abbreviation
3-Hydroxybutanoic acid	$\beta$ -Hydroxybutyric acid	3-OH-4:0
2-Hydroxytetradecanoic acid	$\alpha$ -Hydroxymyristic acid	2-OH-14:0
3-Hydroxytetradecanoic acid	$\beta$ -Hydroxymyristic acid	3-OH-14:0
3-Hydroxy-13-methyltetradecanoic acid		3-OH- <i>iso</i> 15
2-Hydroxyhexadecanoic acid	$\alpha$ -Hydroxypalmitic acid	2-OH-16:0
3-Hydroxyhexadecanoic acid	$\beta$ -Hydroxypalmitic acid	3-OH-16:0
3-Hydroxy-15-methylhexadecanoic acid		3-OH- <i>iso</i> 17
3-Hydroxyoctadecanoic acid	$\beta$ -Hydroxystearic acid	3-OH-18:0
17-Hydroxyoctadecanoic acid	17-Hydroxystearic acid	17-OH-18:0

systematic name of prostaglandin E<sub>1</sub> is 3-hydroxy-2-(3-hydroxy-1-octenyl)-5-oxo-cyclopentaneheptanoic acid. Prostanoids have a cyclopentane ring in their chain, as is found, for example, in prostaglandin E<sub>1</sub> (Figure 13) prostaglandin F<sub>1 $\alpha$</sub> , prostaglandin E<sub>2</sub>, prostaglandin E<sub>3</sub>, and in prostacyclin (PGI<sub>2</sub>).

Thromboxane A<sub>2</sub> (Figure 14) and thromboxane B<sub>2</sub> both have a tetrahydropyran system in their chains.

## Furanoid Fatty Acids

Furanoid fatty acids (FuFAs) have a furanoid ring in their principal chain. One example of a furanoid fatty acid has the formula, C<sub>22</sub>H<sub>38</sub>O<sub>3</sub>, and has the systematic name of 3,4-dimethyl-5-pentyl-2-furanundecanoic acid (Figure 15).

**Figure 13** Prostaglandin E<sub>1</sub> or 3-hydroxy-2-(3-hydroxy-1-octenyl)-5,15,16 acid.

**Figure 14** Thromboxane A<sub>2</sub>.

A large variety of FuFAs are commonly found in the lipids derived from fish and invertebrates.

## Some Synthetic Pesticides and Drugs with a Phenyl or a Naphthyl Ring Attached to the Principal Chain of Fatty Acids

Some synthetic pesticides and drugs have a phenyl or a naphthyl ring attached to the principal chain of fatty acids. The phenoxy acid pesticides, which are derivatives of formic, acetic, propionic, or butyric acids, belong to the synthetic fatty acids (SFAs) family. These acids are usually referred to as phenoxy acids and not as fatty acids, although they should be included in the fatty acids family, because they are derivatives of fatty acids. One such example is (2-methyl-4-chlorophenoxy)acetic acid (Figure 16).

Synthetic drugs with a phenyl or a naphthyl ring system, such as ibuprofen ( $\alpha$ -methyl-4-(2-methyl-propylbenzeneacetic acid) (Figure 17) and naproxen, are also derivatives of fatty acids.

Acitretin (Figure 18) is a synthetic retinoid that is also a fatty acid derivative.

## Fatty Acids with Amino Function in the Principal Chain

Small molecular weight fatty acids with an amino function in the principal chain as found in proteins and peptides are classified as amino acids. It should

**Figure 15** 3,4-Dimethyl-5-pentyl-2-furanundecanoic acid.

**Figure 16** (2-Methyl-4-chlorophenoxy)acetic acid (MCPA).

**Figure 17** Ibuprofen or  $\alpha$ -methyl-4-(2-methylpropyl)-benzeneacetic acid.

**Figure 18** Acitretin.

**Figure 19** 6-Amino-*n*-hexanoic acid.

be recognized that non-protein and peptide AAS still belong to the fatty acids family.

The chemical formula for 6-aminohexanoic acid is  $\text{NH}_2(\text{CH}_2)_5\text{COOH}$ , and its common name is  $\alpha$ -aminocaproic acid (systematic name is 6-amino-*n*-hexanoic acid) (Figure 19). It may be referred to as a fatty acid with an amino group in the principal chain.

### Fatty Acids with an Additional Carboxylic Function in the Principal Chain

Some of the small molecular weight dicarboxylic acids belong to the Krebs cycle acid family. There are many dicarboxylic acids in addition to the Krebs cycle acids. Examples of this family are azelaic acid ( $\text{HOOC}(\text{CH}_2)_7\text{COOH}$ ), brassylic acid (systematic

**Figure 20** Brassylic acid or 1,13-tridecanedioic acid.

name is 1,13-tridecanedioic acid), and thapsic acid (systematic name is 1,16-hexadecanedioic acid) (Figure 20).

### Halogenated Fatty Acids

Marine organisms are the source of brominated fatty acids, such as 6-bromo-5,9-heneicosadienoic and 6-bromo-5,9-docosadienoic acids. Other fatty acids with different halogens, such as F, Cl, and I are also present in marine animals.

### Thio Fatty Acids

An example of the thio fatty acid family is tetradecylthioacetic acid ( $\text{CH}_3(\text{CH}_2)_{13}\text{S-CH}_2\text{-COOH}$ ).

### Stability, Sample Storage and Preparation, and Occurrence of Artifacts

Saturated fatty acids are stable in dry, cold atmospheres. However, the presence of additional functions or unsaturated bonds in the fatty acid chains can make them chemically reactive to the oxygen and moisture in ambient air. The general rule is that fatty acid samples should be kept at temperatures between  $-20^\circ\text{C}$  and  $-70^\circ\text{C}$ , and the samples should be protected from exposure to direct light. To protect the samples against oxygen and moisture, they should be stored under  $\text{N}_2$ , He, or Ar in a sealed container. Unprotected polyunsaturated fatty acids will auto-oxidize rapidly. Any peroxides present in the extraction liquids can produce artifacts.

Fatty acids can be extracted either as FFAs or as BFAs. FFAs are obtained by the hydrolysis of BFAs. Liquid-liquid extraction has been successfully applied in the isolation of several classes of lipids, or of single lipids from complex mixtures. Popular extraction methods for lipids are the 'Folch' extraction technique, or the Bligh and Dyer method. Solid-phase extraction (SPE), and solid-phase microextraction (SPME), are also available as simple and economical time- and solvent-efficient sample preparation methods. Prefractionation can be performed using SPE silica or aminopropyl-silica columns.

The argentation SPE method can be used for the isolation of unsaturated FAs. One very useful

extraction method is the supercritical fluid carbon dioxide extraction technique.

### Ultraviolet, Infrared, and Proton Nuclear Magnetic Resonance Spectroscopic Characteristics of Free Fatty Acids

The carboxyl group in aliphatic FA is a poor chromophore with absorption maximum  $\sim 210$  nm in ethanol, with  $\epsilon = 50$ . The UV absorption properties improve with the presence of unsaturated bonds; especially in the case of conjugated double or triple bonds.

The IR absorption of the functional groups in the principal chains of fatty acids follows general rules, and these rules for given groups are summarized in Table 5.

In the nuclear magnetic resonance (NMR) spectra, the proton signal for the terminal methyl group appears at 9.1 ppm, and the proton signal for the methylene groups in the principal chain appears at  $\sim 8.7$  ppm. The proton signals from other functional groups, if present in the principal chain of the molecule, depend on the solvent.

### Analytical Approach to Separation and Structure Determination of Fatty Acids

Chromatography is the most powerful tool for the separation of complex mixtures of either natural or synthetic origin. Retention time is a tool for the identification of compounds of interest. Five different chromatography techniques will be discussed in this section: liquid–liquid separation, thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), gas chromatography (GC), and supercritical-fluid chromatography (SFC). All these techniques will be discussed in connection with their ability to detect, quantify, and enable structural determination of fatty acids.

Liquid–liquid separation of fatty acids from complex mixtures is the oldest known technique. Hydrolyzed samples are acidified and extracted using a suitable organic phase, which is often diethyl ether.

TLC is used to separate unsaturated fatty acids on plates impregnated with Ag, and is a very popular and useful tool. Less well known is the separation of fatty acids on plates modified with Cu(I), Cu(II), Co(III) ions, and with  $\text{ZnCl}_2$ . TLC may be used as an analytical or preparative tool. Preparative TLC can be used to recover a significant amount of substance for later analysis using other techniques, such as HPLC, GC, or mass spectrometry (MS).

The separation of FFAs using HPLC does not present a problem. A broad spectrum of stationary phases can be used:  $\text{SiO}_2$  phases, stationary phases impregnated with cations, reversed phases, ion-exchange resins, or cellulose. However, detection of underivatized aliphatic fatty acids may be difficult to perform because of a lack of suitable chromophores, luminophores, or fluorophores in the molecule.

Preparation of derivatives to enhance the sensitivity of detectors or to provide useful mass fragmentation for LC–MS analysis may be necessary.

### HPLC Detectors Used in Fatty Acids Analysis

Using an ion-exchange separation in conjunction with a suppressed electrical conductivity detector, based on an injected volume of  $100\ \mu\text{l}$  and a 3:1 signal-to-noise ratio, it is possible to detect haloacetic acids down to the following limits: monochloroacetic acid = 8.0 ppb, dichloroacetic acid = 16.0 ppb, trichloroacetic acid = 80.0 ppb, trifluoroacetic acid = 12.0 ppb, bromoacetic acid = 21.0 ppb, and dibromoacetic acid = 30.0 ppb.

The conductivity detector can be used with gradient elution but is sensitive to pump pulsation, changes in flow rate, and changes in pressure. The analysis should be carried out at constant ionic strength. Refractive index (RI) detectors require isocratic elution. An RI detector is a universal detector.

**Table 5** The IR absorption of the functional groups in the principal chains of fatty acids

Functional groups	Type of absorbance	Frequency ( $\text{cm}^{-1}$ )
Carboxyl $\text{C}=\text{O}$	Normal dimeric carboxylic stretching vibration	1720–1690
$\text{C}-\text{H}$	Stretching vibration superimposed on the $\text{O}-\text{H}$ stretching vibration	2960–2850
$\text{C}-\text{H}$	Bending vibration of the methyl or methylene groups	1375 or 1465
$\text{C}-\text{O}-\text{H}$	In-plane bending vibration	1408
$\text{O}-\text{H}$	Out-of-plane bending vibration of dimeric carboxylic acids	920
$\text{C}=\text{C}$	Unconjugated double bond stretching vibration	1660–1640
$\text{C}\equiv\text{C}$	Triple bond stretching vibration	2260–2100

A new technique developed to detect fatty acids without derivatization, is the use of evaporative light-scattering detector (ELSD). The detector offers several advantages over traditional detectors, as the detection response does not depend on the optical characteristics of the sample. The ELSD can be used with multisolvent gradients. However, the sensitivity is not very high.

Today, ultraviolet detectors (UVDs) are commonly used for the detection of natural and derivatized fatty acids.

The fluorescence detector (FD) is one of the most sensitive detectors in use, and can record both excitation and emission spectra. The excitation spectra are identical to the UV-visible absorption spectra; however, emission spectra can provide additional information. Detectors that are used to detect isotope-labeled molecules measure the radioactivity present. Other analytical instruments, such as IR spectrometers, mass spectrometers, NMR spectrometers, electron spin resonance spectrometers, plasma emission and plasma absorption spectrometers can be connected to HPLCs for use as detectors, to provide further information on molecular structure.

## Supercritical-Fluid Chromatography

From a technical perspective, SFC is similar to HPLC; however, the mobile phase is a supercritical fluid. The SFC method possesses all the advantages of the HPLC method, and some advantages of the GC technique. High-sensitivity detectors used in HPLC and GC can also be used in SFC. However, some restrictions on the detectors arise from the use of condensed gas as the supercritical fluid. The most widely used ELSD.

Modification of the mobile phase with water or an organic solvent can improve the separations. However, it is not possible to use the FID when organic solvent is used as a modifier.

## Derivatization to Enhance Spectrophotometric Detection for HPLC Analysis

The aim of derivatization is to introduce into the molecule a suitable chromophore or fluorophore. Precolumn and postcolumn derivatization are used in HPLC. Some of the reagents, their properties, separation conditions, and reactions are summarized below.

Phenacyl bromide or (2-bromoacetophenone) (PB). Reactions with phenacyl bromide afford quantitative yields, and are easily carried out. Detection

limits are in the nanogram range. Maximum detection wavelength is 242 nm.

A wide choice of stationary phases is available for separation, such as reversed-phase or silver-ion impregnated phases. The separation of phenacyl derivatives of saturated, monoenoic, polyenoic, and monohydroxy fatty acids, and of the geometric isomers of fatty acids is possible.

Other phenacyl reagents are: *p*-bromophenacyl bromide, or  $\alpha$ -bromo-*p*-bromoacetophenone, *p*-chlorophenacyl bromide, or  $\alpha$ -bromo-*p*-chloroacetophenone, *p*-nitrophenacyl bromide, or  $\alpha$ -bromo-*p*-nitroacetophenone, *m*-methoxyphenacyl bromide, or  $\omega$ -bromo-3-methoxyacetophenone.

[*p*-(9-Anthroyloxy)]phenacyl bromide is the reagent of choice, as it has a high detection sensitivity, a detection wavelength maximum of 253 nm, and  $\epsilon$  of  $174,280 \text{ mol}^{-1} \text{ l}^{-1} \text{ cm}^{-1}$ .

## Derivatization of Monohydroxy Fatty Acids for HPLC Analysis

Derivatives of HFAs can be hydroxamic acids, phenacyl derivatives, nitrobenzoyl derivatives, and naphthacyl derivatives. Derivatization of the hydroxy group can be achieved using 1-anthroynitrile. The naphthacyl derivatives can be separated by reversed-phase chromatography and detected at 246 nm, with a detection limit of  $\sim 0.1 \text{ ng}$ .

PBr derivatives, exhibit fluorescence when excited with at 375 nm, emission wavelength at 470 nm. It is possible to achieve femtomolar detection limits by using 4-bromomethyl-7-methoxycoumarin (BrMMC) derivatives and laser excitation.

Other reagents used are: 4-bromomethyl-7-acetoxycoumarin (BrMAC), 3-Bromoacetyl-7-methoxycoumarin (BrAMC). The use of BrAMC allows the derivatization of fatty acids at room temperature. BrAMC has a higher reactivity than other bromomethylcoumarins: 4-bromomethyl-6,7-dimethoxycoumarin, 4-bromomethyl-6,7-methylene-dioxycoumarin, 4-bromomethyl-7,8-benzocoumarin, 4-diazomethyl-7-methoxycoumarin, and 7-(diethyl-amino)-coumarin-3-carbohydrazide.

Separation of  $C_1$  to  $C_{20}$  fatty acids as 9-(2-hydroxyethyl)carbazole derivatives can be achieved by HPLC using gradient elution on a C18 column in a relatively short time. The  $\lambda_{\text{ex}}$  was at 293 nm, and the maximum fluorescence emission for the derivatized fatty acids was at 365 nm. Sensitive detection is possible by fluorescence excitation at  $\lambda_{\text{ex}} = 293$  or 335 nm and emission at 365 nm.

Derivatization with 5-bromomethylfluorescein (5-BMF). Allows use of UV, conductivity, and also laser-induced fluorescence (LIF) detectors.

## GC Analysis of Fatty Acids

The evaporation temperature of high-molecular weight FFAs is close to their decomposition temperatures (see Table 1). Thus, the adsorption of FFAs on the injector or syringe can be a problem as a memory effect. The separation of a broad range of FFAs by GC is shown in Figure 21.

Derivatization of fatty acids is performed to increase the volatility of the products, to reduce dimerization in the vapor phase, to reduce the adhesion to the apparatus' construction materials and columns, to improve separation, and to reduce tailing. The

**Figure 21** GC separation of underivatized saturated and unsaturated FFAs. Peaks: C<sub>6:0</sub> = caproic acid; C<sub>8:0</sub> = caprylic acid; C<sub>9:0</sub> = nonanoic acid; C<sub>10:0</sub> = capric acid; C<sub>11:0</sub> = undecanoic acid; C<sub>12:0</sub> = lauric acid; C<sub>14:0</sub> = myristic acid; C<sub>16:1</sub> = palmitoleic acid; C<sub>16:0</sub> = palmitic acid; C<sub>18:0</sub> = stearic acid. (Reproduced with permission from Brondz I, Olsen I, and Greibroekk T (1983) Direct analysis of free fatty acids in bacteria by gas chromatography. *Journal of Chromatography* 274: 299–304.)

importance of derivatization is that it can improve the detection limit. It can also provide additional, or in some cases clearer, information under fragmentation in MS experiments.

## Derivatizations to Enhance Volatility, to Reduce Adhesion, and to Reduce Tailing

Esterification can increase the volatility of fatty acids, reduce dimerization in the vapor phase, and reduce adhesion. Esterification improves the peak configuration, the separation, and sample detectability.

The methyl, ethyl, propyl, *iso*-propyl, *n*-butyl, and *iso*-butyl esters of fatty acids are recommended.

Methylation of fatty acids is a well-known technique. A wide range of methylation and transesterification procedures are available in the literature. Defined IUPAC methods for the preparation and GC analysis of fatty acid methyl esters (FAMES) have been published. The methylation with diazomethane, as modified by Schlenk and Gelleman is in common use. Under the proper conditions, methylation with diazomethane gives good results.

It is known that methylation with diazomethane selectively methylates FFAs in the presence of FA esters. Caution is required, as diazomethane is a dangerous substance. Under inappropriate conditions, derivatization with diazomethane leads to the formation of artifacts. Functional groups such as phenol, enol, and carbonyl, or olefinic bonds can be affected. The less-dangerous methylation agents such as trimethylsilyldiazomethane (TMS-CHN<sub>2</sub>) and lithiated TMS-CHN<sub>2</sub> have been suggested to replace diazomethane. Benzyl esters can be produced by the use of phenyldiazomethane.

Anhydrous MeOH in the presence of an electrophilic catalyst, such as HCl, concentrated sulfuric acid, dichloroacetic acid, trifluoroacetic acid, benzene sulfonic acid, polyphosphoric acid, *p*-toluene sulfonic acid, thionyl chloride, and perchloric acid is often used for the methylation of fatty acids.

Adding liquid acetyl chloride to anhydrous MeOH to prepare anhydrous MeOH-HCl is a simple procedure that is recommended. Hydrochloric acid, H<sub>2</sub>SO<sub>4</sub>, and BF<sub>3</sub> in anhydrous MeOH can be used for acid-catalyzed transmethylation. In addition, transmethylation can be catalyzed by KOH, NaOCH<sub>3</sub>, and NaOH in MeOH. Cyclopropane fatty acids are sensitive to acid-catalyzed methanolysis, and artifacts can be produced. Alkaline esterification is preferred when the sample contains cyclopropane fatty acids. The preparation of ethyl, propyl, *iso*-propyl, *n*-butyl, *iso*-butyl-, and benzyl esters for GC

analysis of mixtures of low and high molecular weight fatty acids is preferred to methyl esters. It is possible to obtain satisfactory results using boron trifluoride ( $\text{BF}_3\text{-MeOH}$ ) and boron trichloride ( $\text{BCl}_3\text{-MeOH}$ ) for the methylation of cyclopropane fatty acids. Sometimes, it is necessary to perform the methylation of carboxylic acids in an aqueous phase, and then trimethyloxonium tetrafluoroborate (TMO) is the reagent of choice.

## Derivatization of Hydroxy Fatty Acids for GC Analysis

Alcoholic functional groups in HFAs can be derivatized using a trifluoroacetic acid anhydride (TFAA)–pyridine mixture after esterification of the carboxylic function. Methyl iodide ( $\text{CH}_3\text{I}$ ) can be used for preparation of the methyl esters of HFAs.

Trialkylsilylation of HFAs was popular; however, it has drawbacks. *N*-Trimethylsilylimidazole (TSIM) preferentially derivatizes hydroxyl groups. TSIM can be used for the trimethylsilylation of HFAs in the presence of water. *N*-Methyl-*N*-trimethylsilyl-heptafluorobutyramide (MSHFBA) does not produce any deposit in a flame ionization detector, and can be used for the silylation of acid and alcohol functions.

Hexamethyldisilazane (HMDS) is not very effective by itself, but in combination with TMCS, it is a fast and quantitative silylating reagent. *N*-(*tert*-butyldimethylsilyl)-*N*-methyltrifluoroacetamide (MTBSTFA) can react with the hydroxyl on HFAs, and with carboxyl to form relatively stable *tert*-butyldimethylsilyl derivatives which are useful in GC–MS analysis.

Tetramethylammonium hydroxide, tetramethylammonium acetate, tetramethylanilinium hydroxide, trimethylsulfonium hydroxide, and tetramethylguanidine have been used in intrainjector derivatization as shown in Figure 22. This technique has become popular for thermally assisted hydrolysis, and in the methylation of complex mixtures of lipids or for a complex matrix, such as bacterial cell walls. Tetramethylguanidine (TMG) also reacts with FFA to produce methyl esters in the hot GC injector.

*N,N*-Dimethylformamide dialkyl acetals in mixture with pyridine can react with fatty acids in a hot GC injector to methylate fatty acids. However, the hydroxyl groups of HFAs do not react.

## Derivatives to Enhance Detectability of Fatty Acids in GC Analysis

It is well known that formic acid has a low FID response. Derivatization to form the  $\alpha$ -hydroxyphosphonate ester permits the use of NPD for detection

**Figure 22** GC chromatogram of TMAH intrainjector derivatized phenoxy acids. Peaks: 1 = 2-phenoxypropionic acid; 2 = *p*-fluorophenoxyacetic acid; 3 = 2-methylphenoxyacetic acid; 4 = 3-methylphenoxyacetic acid; 5 = 4-methylphenoxyacetic acid; 6 = 2-formylphenoxyacetic acid; 7 = 2,5-dimethylphenoxyacetic acid; 8 = 2-(4-chlorophenoxy)propionic acid; 9 = 2,4-dimethylphenoxyacetic acid; 10 = 2-methoxyphenoxyacetic acid; 11 = 4-phenoxybutyric acid; 12 = 3-methoxyphenoxyacetic acid; 13 = 4-methoxyphenoxyacetic acid; 14 = 2-(4-chloro-2-methylphenoxy)propionic acid; 15 = 4-chloro-2-methylphenoxyacetic acid; 16 = 2,4-dichlorophenoxypropionic acid; 17 = iodophenoxyacetic acid; 18 =  $\alpha$ -(2,4,5-trichlorophenoxy)propionic acid; 19 = 2,4,5-trichlorophenoxyacetic acid. (Reproduced with permission from Brondz I and Olsen I (1992) Intra-injector formation of methyl esters from phenoxy acid pesticides. *Journal of Chromatography* 598: 309–312.)

in the low picogram range. The 2,2,2-trichloroethyl esters of FAs can be detected using an ECD at high sensitivity in the nanogram range. The pentafluorobenzyl bromide (PFB-Br) derivatives of fatty acids have been detected using an ECD in the same sensitivity range. The use of iodomethyltetramethyldisiloxane esters allows the more sensitive detection using an ECD than do chlorine or bromine derivatives.

## Derivatives to Facilitate MS Fragmentation Patterns

Cyanomethyl esters are produced in the reaction between fatty acids and iodoacetoneitrile or bromoacetoneitrile. The cyanomethyl esters produce visible molecular ions  $\text{M}^+$ , and characteristic fragments, e.g.,  $[\text{M} - 15]^+$ ,  $[\text{M} - 31]^+$ ,  $[\text{M} - 43]^+$ , and  $[\text{M} - 99]^+$ .

**Figure 23** McLafferty rearrangement ion  $m/z$  186 of the trifluoroacetic acid anhydride derivatives of 2-hydroxy fatty acid methyl esters.

### Localization of the Hydroxyl in the Principal Chain

HPLC–MS or GC–MS are techniques that are normally used for the localization of hydroxyl groups in the principal chains of HFAs. A characteristic fragment ion at  $m/z = 186$  for trifluoroacetyl derivatives indicates the presence of an  $\alpha$ -hydroxyl group (Figure 23).

Derivatization with dimethyloxazoline (DMOX) assists in the correct localization of the hydroxyl group in the principal chain of the HFAs.

### Localization of Unsaturation or Epoxidation

The techniques used for the localization of unsaturation or rings in the principal chain of fatty acids are the von Rudloff oxidation and the oxidation reactions described by Ackman. The products of these reactions can be analyzed using GC or GC–MS. However, the low molecular weight fatty acids produced in the reactions can be lost. Preparation of pyrrolidids from unsaturated fatty acids avoids this problem. DMOX derivatives can also help in the localization of unsaturation, epoxidation, and hydroxyl groups.

### Localization of Branching

The localization of branching is achieved by careful comparison of the MS fragmentation of normal and branched fatty acids. The intensity of some fragments is a useful diagnostic tool. However, a reduction of esters to alcohols can improve the interpretation.

### Localization of the Keto Function in Fatty Acids

The localization of keto functions in KFA's can be achieved by conversion to methyl hexahydro-3-alkyl-6-thioxo-1,2,4,5-tetrazine-3-alkanoates.

## Polar Lipids

**M H Gordon**, The University of Reading, Reading, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Polar lipids occur as complex mixtures in biological membranes. This category includes phospholipids,

sphingolipids, glycolipids, and sulfolipids. Each of these classes comprises molecules that vary in the fatty acids and the polar groupings that are present. Thus, the phospholipids include phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, phosphatidylglycerol, and phosphatidic acid as well as plasmalogens containing phosphate; sphingolipids include sphingosine, sphingomyelin, ceramides, gangliosides, cerebroside, and cerebroside sulfates; sulphoquinovosyldiacylglycerol and mono- and di-galactosyldiacylglycerols are also members of the polar lipids class (**Figure 1**).

The great complexity of natural lipid mixtures normally necessitates the use of some form of chromatography for their separation. Since the nonpolar lipid molecules are often better resolved and recovered from chromatographic systems, the polar head group may be removed or masked with nonpolar groups prior to the chromatographic separation.

## Solubility and Extraction of Polar Lipids

Polar lipids are only sparingly soluble in hydrocarbon solvents but most polar lipids dissolve in more polar solvents such as methanol, ethanol, or chloroform. Chloroform–methanol mixtures dissolve most polar lipids but polyphosphoinositides or lysophospholipids are poorly soluble in this solvent mixture. Water–methanol mixtures may dissolve significant amounts of the most polar lipids such as gangliosides. Acetone is a poor solvent for phospholipids but glycolipids are more soluble in this solvent.

Extraction of lipids with chloroform–methanol (2: 1) as in the Folch or Bligh and Dyer procedures is commonly sufficient to extract most lipids from biological tissues. The Folch procedure removes contaminating compounds by shaking the solvent mixture with 25% of their volume of potassium chloride solution. The lower chloroform-rich phase contains the purified lipids whilst the upper phase contains nonlipid contaminants together with gangliosides and some glycolipids. Gangliosides can be removed from the upper phase by dialysis and lyophilization.

## Detection and Quantification of Polar Lipids

Lipids are commonly characterized by their solubility properties, i.e., they can be extracted by the Folch or Bligh and Dyer procedures. The next stage in the analytical procedure for mixtures involves

chromatography, commonly thin-layer chromatography (TLC), and a range of selective spray reagents are useful for detecting polar lipids (see **Table 1**).

The concentration of phospholipids in a lipid mixture can be estimated as phosphate after ashing the sample. The ash can be treated with nitric acid, dissolved in hydrochloric acid, and the phosphorus determined by inductively coupled plasma-atomic emission spectrometry at 214.9 nm. Alternatively, the phosphorus can be determined by atomic absorption spectrometry at 213.547 nm with a graphite furnace. Traditional methods for phosphorus determination include the precipitation of phosphate as quinolinium molybdophosphate and gravimetric determination, or colorimetric methods such as the reaction with ammonium molybdate and acidic ammonium vanadate solution followed by determination of the absorbance at 460 nm.

The glycosidic bond of glycolipids is readily hydrolyzed by acid, and the carbohydrates liberated can be analyzed by instrumental methods, e.g., gas chromatography (GC), liquid chromatography (LC), or colorimetric procedures can be used. In one colorimetric procedure, the total amount of hexose units in a glycolipid can be quantified by reaction with anthrone in concentrated sulfuric acid and determination by the absorbance at 635 nm.

## Spectroscopic Methods

Spectroscopic methods are mainly useful for identifying pure lipids. Mass spectrometry (MS), nuclear magnetic resonance (NMR) spectroscopy, and infrared (IR) spectroscopy provide useful information but the ultraviolet (UV) region is mainly useful for LC detection of unsaturated lipids by the weak absorbance of *cis*-unsaturated bonds at 205 nm. Although MS may give a molecular ion and fragments that allow identification of the fatty acids in glycerolipids, identification of the positional distribution of the fatty acids may require enzymic hydrolysis with phospholipase A<sub>2</sub>, which hydrolyzes fatty acids at position 2 of glycerophospholipids.

### Nuclear Magnetic Resonance Spectroscopy

The <sup>1</sup>H, <sup>13</sup>C, and <sup>31</sup>P NMR spectra of complex lipids have been studied. <sup>1</sup>H and <sup>13</sup>C provide useful information for single phospholipids but due to the complexity of the spectra, it is not possible to use these techniques to analyze mixtures.

The amide proton of sphingosine and its derivatives such as cerebroside shows a doublet at low field (~7.6 ppm, *J* = 9 Hz), which is exchangeable

Figure 1 Polar lipids.

with  $\text{D}_2\text{O}$ . The fatty acid substituent shows a long methylene chain at 1.3 ppm, with the terminal methyl group at 0.85 ppm. Acetylation of glycolipids allows the number of sugar residues to be determined

from the ratio of the integral of the acetyl signal at  $\delta$  1.97–2.5 ppm and other characteristic signals, e.g., the amide proton. High-resolution  $^1\text{H}$  NMR of glycosphingolipids using spin decoupling difference

**Table 1** Reagents for detection of lipids in TLC

Reagent	Color	Specificity
50% H <sub>2</sub> SO <sub>4</sub> in methanol Heat at 110°C	Brown-black	Nonspecific
0.25% Potassium dichromate in 15% H <sub>2</sub> SO <sub>4</sub> Heat at 125°C/30 min	Brown-black	Nonspecific
Iodine vapor	Brown	Nonspecific
0.01% 2',7'- Dichlorofluorescein in ethanol/UV irradiation	Pale	Nonspecific
Molybdic anhydride, H <sub>2</sub> SO <sub>4</sub> molybdenum	Blue	Phospholipids
Ammonium pentachlorooxomolybdate/ H <sub>2</sub> SO <sub>4</sub>	Blue	Phospholipids
Ninhydrin/ <i>n</i> -butanol/acetic acid. Heat at 110°C	Red	Amino group
Basic bismuth nitrate/acetic acid/potassium iodide	Orange	Choline
Anthrone/thiourea/H <sub>2</sub> SO <sub>4</sub> Heat at 110°C, 10 min	Red-purple	Glycolipid
Diphenylamine/HCl/acetic acid Heat at 105°C, 5 min	Blue-gray	Glycolipid
Resorcinol/copper sulfate/HCl Heat at 95°C, 30 min	Blue-purple	Ganglioside

spectroscopy or the nuclear Overhauser effect allows identification of most of the sugar ring protons for glycosphingolipids.

<sup>13</sup>C NMR with broadband <sup>1</sup>H decoupling is useful in identifying the sugar residue in glycolipids. <sup>13</sup>C NMR spectroscopy of phospholipids in solution has also been reported. Changes in the polar head group do not affect the chemical shifts of carbon atoms in the rest of the molecule. The carbon  $\alpha$  to the phosphate group in the polar head group is well separated from the  $\beta$  carbon atom. Chemical shifts of C $\alpha$  and C $\beta$  are 59.58 and 66.80 ppm for phosphatidylcholine and 62.16 and 40.80 ppm for phosphatidylethanolamine. The methyl groups in the polar head group of phosphatidylcholine have a chemical shift of 54.47 ppm. Coupling between <sup>13</sup>C and <sup>31</sup>P gives information about the conformation of phospholipids in the region of polar head groups.

High-resolution <sup>31</sup>P NMR spectra of phospholipids are typically determined with spectrometers operating at 202.4 MHz and a magnetic field of 11.75 T. The use of detergents has been shown to narrow the <sup>31</sup>P linewidth considerably. Proton broadband decoupling removes splitting due to <sup>31</sup>P-<sup>1</sup>H coupling, and signals of <3.5 Hz width at half-height can be obtained. Phosphodiester resonance signals normally occur in the chemical shift range of +1.5 to -1.5 ppm relative to 85% inorganic orthophosphoric acid. Lyso derivatives

show an increase in  $\delta$  of ~0.5 ppm. The signals due to each family of phospholipids are well separated and integration can be used to quantify each family of phospholipids. The chemical shifts of the base and conjugate acid forms of phospholipids in aqueous media differ by ~0.5 ppm.

Also, <sup>31</sup>P NMR is useful for studying the conformation and dynamics of phospholipid head groups as well as lipid polymorphism.

### Mass Spectrometry

Degradation and derivatization of complex lipids commonly interferes with the complete analysis of intact molecules when electron impact is used for ionization due to the low volatility and thermal lability of these molecules.

Various classes of phospholipids have been examined by field-desorption MS. Most phospholipids except phosphatidylserine provide intense MH<sup>+</sup> ions under these conditions but many ions of higher mass may also occur due to association of the polar groups.

Desorption chemical ionization with ammonia provides useful information about fatty acyl groups, while fast atom bombardment (FAB) gives diagnostic peaks about the various head groups. Ammonia is better than methane as a reagent gas for chemical ionization, since it provides more useful fragmentations. The desorption chemical ionization spectra of phospholipids other than phosphatidylserines show protonated molecular ions. Phosphatidylcholines show an MH<sup>+</sup>-42 peak arising from MH<sup>+</sup> - N-(CH<sub>3</sub>)<sub>3</sub> + NH<sub>3</sub>. Phospholipids cleave at the phosphorus-glycerol oxygen linkage and ions are evident from the 1,2-diacylglycerol ammonia adduct, which occurs together with protonated ions and ions formed by the elimination of water from the diacylglycerol. The latter species also suffers additional loss of a fatty acyl chain.

In addition, FAB-MS gives protonated ions for phospholipids other than phosphatidylserine. Dimeric ions plus association ions are formed. Common fragments include [H<sub>3</sub>PO<sub>4</sub> + H]<sup>+</sup>, [M - H<sub>2</sub>PO<sub>4</sub>]<sup>+</sup>, [M + H - fatty acid]<sup>+</sup>, [M + H - fatty acyl chain]<sup>+</sup>. Phosphatidylcholines give the choline phosphate ion of mass 184 as the base peak. A base peak of 142 is evident in the mass spectra of phosphatidylethanolamines.

It is clear that the mass spectral behavior of phospholipids using desorption chemical ionization and FAB techniques provides valuable information about their molecular structures.

These techniques are also useful in determining the structure of glycolipids where loss of a sugar residue is a characteristic ion.

## Infrared Spectra

Most complex lipids are acylglycerol derivatives and therefore their IR spectra show bands characteristic of esters and hydrocarbon chains (Table 2).

The phosphate group of phospholipids shows a strong  $\text{P}=\text{O}$  stretching band at  $1350\text{--}1250\text{ cm}^{-1}$ , which is sometimes a doublet and may be shifted to lower frequencies with an increase in intensity. Vibration of the  $\text{P}\text{--}\text{OH}$  group gives rise to absorption at  $2700\text{--}2560\text{ cm}^{-1}$ . Differences occur in the  $\text{P}=\text{O}$  stretching frequency between phosphatidylethanolamine ( $1227\text{ cm}^{-1}$ ) and phosphatidylserine ( $1220\text{--}1180\text{ cm}^{-1}$ ).

The *trans* double bond of sphingosine derivatives gives an absorbance band at  $970\text{ cm}^{-1}$ , although another band occurs at this frequency in some sphingosine derivatives such as sphingomyelin and this interferes with the use of this band for quantitative determination of the *trans* unsaturated content.

The IR spectra of complex lipids are not sensitive to variations in acyl chain length, unsaturation, or the presence of  $\alpha,\beta$ -unsaturated ether links.

However, the nitrogenous bases of phospholipids can be identified by their IR absorption spectra in the region of  $900\text{--}1100\text{ cm}^{-1}$ . Free amine groups as present in phosphatidylserine or phosphatidylethanolamine show a single sharp absorption band at  $1075\text{ cm}^{-1}$ . Quaternary amines such as phosphatidylcholine or sphingomyelin have a doublet at  $1087$  and  $1053\text{ cm}^{-1}$  and a sharp band at  $961\text{ cm}^{-1}$ . In addition, the range  $1430\text{--}1820\text{ cm}^{-1}$  shows characteristic features.

The spectrum of a solid phospholipid may show fine structure at low temperatures, which disappears on heating. For example, the  $\text{CH}_2$  rocking band at  $720\text{ cm}^{-1}$  of 2,3-dipalmitoyl-DL-1-phosphatidylethanolamine is split into a doublet at low temperatures but this band changes into a singlet at room temperature. This is similar to the behavior observed with soaps and is due to the flexing and twisting of the hydrocarbon group on heating. At some temperature below the melting point of the lipid, the fine structure disappears completely due to movement of the acyl chain.

**Table 2** Assignment of acylglycerol bands in infrared spectra

Vibration	Wavenumber range ( $\text{cm}^{-1}$ )
C—H stretch ( $\text{CH}_2$ and $\text{CH}_3$ )	3030–2967
C=O stretch	1751–1720
C—H bend ( $\text{CH}_2$ and $\text{CH}_3$ )	1464–1453
C—H bend (symmetrical deformation of $\text{CH}_3$ )	1383–1361
C—H in plane wagging or rocking of $\text{CH}_2$	1261–1250
C—O stretch	1179–1166
$\text{CH}_2$ rocking	730–717

The infrared spectra of solid phospholipids vary due to the occurrence of polymorphism. The ester carbonyl frequency and bands between  $670$  and  $1050\text{ cm}^{-1}$  may shift due to the variations in the crystal structure arising from different polymorphs.

## Chromatographic Separation of Intact Lipids

Removal of residual water and other nonlipid material may be achieved with solid-phase extraction cartridges. The major lipid classes namely neutral lipids, glycolipids, and phospholipids are commonly separated using column chromatography, TLC, or LC as a preliminary separation procedure. Column chromatography with silicic acid has been widely used to separate phospholipids, cerebroside, and sulfatides. The degree of hydration of the silicic acid has an important influence on the quality of the separation. Sufficient water is required to avoid tailing of the lipid bands, but quantities of water above  $\sim 5\%$  lead to poorer retention and separation. Detection of lipids from the chromatographic column may be gravimetric, or it may involve the removal of aliquots from each fraction for testing with acidified potassium dichromate, which suffers a reduction in absorbance at  $350\text{ nm}$  in the presence of lipids. Diethylaminoethylcellulose chromatography is a useful alternative to adsorption chromatography for the separation of polar lipids. This form of chromatography depends partly on ion exchange and partly on adsorption.

## Thin-Layer Chromatography

TLC is probably the most common method for the separation of polar lipids. One-dimensional TLC is commonly used for rapid group separation or for small-scale preparative purposes, whilst two-dimensional TLC gives improved resolution. Silica gel G plates developed in chloroform–methanol–water (25:10:1 by volume) give useful separations of phospholipids. Solvent mixtures containing acetic acid or ammonia, e.g., chloroform–methanol–28% aqueous ammonia (65:35:5) or chloroform–acetone–methanol–acetic acid–water (10:4:2:2:1) are among the wide range of solvent mixtures that have been used for TLC separations of polar lipids.

For the separation of glycolipids, either chloroform–methanol–water or *n*-propanol–water are commonly used. The mobilities of acidic glycolipids such as gangliosides and the width of their bands are affected by the presence of salts or ammonia, whereas neutral glycolipids are well separated both in the presence and absence of these additives. The

improved resolution of high-performance TLC is valuable in the separation of complex polar lipid mixtures.

Lipids separated on TLC plates are usually detected with chromogenic or fluorescent reagents. Spraying with acidified potassium dichromate followed by heating at 125°C, which yields brown–black spots, or treating with iodine vapor are nonspecific methods of detecting lipids and other organic compounds. Spraying with a fluorescent reagent such as 2',7'-dichlorofluorescein solution followed by inspection under a UV lamp is another nonspecific method. Specific reagents for the detection of phospholipids, amino group-containing lipids, choline-containing lipids, glycolipids, and gangliosides are shown in Table 1.

Polar lipids separated by TLC are commonly quantified by densitometry or the lipids may be scraped off and quantified by colorimetry or gas chromatography after derivatization. The Iatroscan TLC-flame ionization detector system is well suited to the quantification of polar lipids. In this procedure, TLC is performed on quartz rods coated with silica. The rods are then passed through a flame ionization detector to quantify each lipid band in turn.

### Liquid Chromatography

Normal-phase LC analysis is an effective method of separating phospholipid classes. Columns containing silica (3–10 µm diameter) as the stationary phase are used in combination with a mobile phase of chloroform–methanol–water; acetonitrile–methanol–water; or hexane–isopropanol–water. UV absorbance at 205 nm due to the carbon–carbon double bonds of

the fatty acids in the phospholipid can be used as the basis of detection for the latter two solvent mixtures. A light scattering detector or a flame ionization detector is required if chloroform is present. After separation of phospholipids into classes by normal-phase chromatography, reversed-phase LC with a C18 column can be used to separate the individual molecular species of a particular class. Effective separation of several classes of polar lipids can be achieved by HPLC (Figure 2).

Phospholipids can be separated from other polar lipids by normal-phase LC. Thus, on isocratic elution with acetonitrile–methanol–sulfuric acid (135:5:0.2), phosphatidylinositol elutes first followed by monogalactosyldiacylglycerol, *N*-acylphosphatidylethanolamine, *N*-acyl-lysophosphatidylethanolamine, phosphatidylethanolamine, and digalactosyldiacylglycerols.

There are very few reports of the application of supercritical fluid chromatography to the analysis of polar lipids in the literature.

### Electrophoresis

The importance of phospholipids in biological membranes and in cell signaling has provided a strong impetus for the development of methods capable of analyzing the complex mixtures that are present in biological systems. Electrophoresis using methods based on micellar electrokinetic capillary chromatography (MEKC) has strong potential for the separation of complex lipids. Baseline resolution of mixtures of phosphatidylethanolamine, phosphatidylserine, and lysophosphatidylethanolamine was achieved in 7 min using MEKC following labeling with a fluorogenic dye.

**Figure 2** HPLC chromatogram of chloroform-extracted wheat flour lipid analyzed on a silica column (5 µm; 100 mm × 4 mm) with gradient elution with a mixture of (A) hexane–tetrahydrofuran 99:1; (B) isopropanol, and (C) water. 1 = triacylglycerols; 2 = free fatty acids; 3 = diacylglycerols; 4 = monoacylglycerols; 5 = acylated steryl glycosides; 6 = monogalactosyldiacylglycerols; 7 = monogalactosylmonoacylglycerols; 8 = digalactosylmonoacylglycerols; 9 = digalactosyldiacylglycerols; 10 = unidentified; 11 = phosphatidylglycerol; 12 = phosphatidylethanolamine; 13 = phosphatidylcholine.

## Enzymatic Hydrolysis of Phospholipids

Glycerophospholipids may be hydrolyzed to phosphatidic acid with phospholipase D, or to diacylglycerols with phospholipase C. The latter hydrolysis allows the analysis of phospholipids by TLC, GC, or LC, whereas the hydrolysis with phospholipase D produces molecules that are best analyzed by LC.

If silver nitrate is incorporated into the silica gel used to coat a TLC plate, good separations of diacylglycerols according to degree of unsaturation can be achieved on elution with a mobile phase such as chloroform–methanol (99:1).

Silver ion chromatography has been extended to LC and is useful for separating polar lipids differing in unsaturation of the fatty acids. Thus, ceramides containing saturated fatty acids have been separated from ceramides containing unsaturated fatty acids on a column based on silver ions bound to an ion-exchange support.

## Stability of Polar Lipids

Polar lipids commonly include polyunsaturated fatty acids and consequently are sensitive to oxidation. Addition of an antioxidant such as tertiary butylhydroquinone is recommended during the isolation of polar lipid mixtures. If the polar lipids are to be extracted from biological tissues, extraction should preferably be performed as soon as possible after removal from the living organism in order to avoid enzyme-catalyzed changes in the lipids. If this is not possible, the samples should be stored in sealed glass containers under nitrogen at  $-20^{\circ}\text{C}$ . It may also help to inactivate lipases by plunging the sample into boiling water or boiling with acetic acid or isopropanol. Careful handling of the polar lipids is required at all stages during the isolation and analysis in order to avoid oxidation. The analysis of polar lipids is a very challenging exercise due to the complexity of natural lipid mixtures, but recent developments in analytical techniques, especially the widespread use of LC and the development of  $^{31}\text{P}$  NMR spectroscopy, have had a big impact on this area of analysis.

## Introduction

Lipid measurements in body fluids are of great interest because they can indicate abnormalities in

metabolite levels and transport, and provide valuable clues for clinical diagnosis. A detailed determination of the lipid composition of biological fluids differs little from tissue lipid analysis, which requires combinations of two or more analytical systems and is laborious and time consuming. However, much information about the lipids in biological fluids can be frequently obtained by rapid total lipid profiling that is possible following a limited preliminary work-up. Thus, thin-layer chromatography (TLC) and gas-liquid chromatography (GC) continue to be extensively utilized for this purpose, while more recently, high-performance liquid chromatography (HPLC) and tandem mass spectrometry (MS/MS) have also been employed. Both GC and HPLC are readily combined with MS as online GC-MS and LC-MS for multi-component analyses of body fluids.

Most determinations of lipids in biological fluids are presently being performed using state-of-the-art methodology. The analytical routines have usually been adopted from tissue analyses, but in a few instances specific methods have been developed for biofluid analyses (e.g., plasma total lipid profiling). While the lipid analyses of a few biofluids have been reviewed in depth, in most instances background reviews are available only in leading applied publications. As a result, the present encyclopedic account is based largely on reports of the more successful analyses of lipids in the major biofluids. Combination of HPLC with electrospray MS has proved to be the most generally applicable methodology, but other chromatographic and mass spectrometric techniques have also served well for specific applications. Recently, nuclear magnetic resonance (NMR) and LC-NMR have been adopted for this purpose and offer special advantages for phospholipid class analyses. Unfortunately, the modern methods of lipid analyses have not provided the most reliable quantitative results, occasionally contradicting each other. In such instances, resolution of the problem of quantification has been sought in conventional chemical analyses and radio- or stable isotope dilution assays.

## Improvements in Strategy

Improvements in the strategy of analyses have come from the realization that body fluids have structure and are made up of different physicochemical phases, which can be separated into subfractions for a more meaningful assay than that provided by a total fluid analysis. Thus, blood can be subdivided by centrifugation into cellular (erythrocytes, lymphocytes, and platelets) and noncellular (plasma or serum) fractions, while plasma or serum can be subdivided

into various lipoprotein subfractions (high-density lipoprotein (HDL), low-density lipoprotein (LDL), very low density lipoprotein (VLDL), etc.) by ultracentrifugation. In other instances, the protein molecules of a biofluid may be resolved by two-dimensional gel chromatography and the lipid ligands associated with it determined. Furthermore, the total lipid extracts themselves can be resolved into polar and nonpolar fractions by silica gel cartridge separation prior to a quantitative lipid profiling. Finally, depending on the analytical needs, the lipid analysis of a biofluid can be performed on a highly concentrated sample, which would favor the detection of minor components, or on specific components (cholesterol, unesterified fatty acids) of the total lipid extract or the original biofluid (differential extraction and derivatization). A comparable prefractionation can be performed on milk, lymph, bile, and other body fluids and cell cultures. In addition, major developments in instrumental analyses now permit precise analyses on progressively smaller biofluid samples, which have permitted a revision and simplification of the original strategies for lipid analyses in biofluids. As a result, the isolation of specific protein components of a biofluid has been occasionally combined with a mass spectrometric identification of its lipid ligand. In other instances, the biofluid may be analyzed following incubation with endogenous or exogenously added enzymes.

Of equal or greater importance has been the replacement of the laborious and time-consuming multidimensional-chromatographic systems by flow injection and matrix-assisted laser-desorption ionization mass spectrometry (MALDI-MS) and MS/MS. These developments have been rivaled by the recent explosion in the application of NMR methodology for identification and quantification of lipid classes in body fluids. With these advances in the analytical technology has come the possibility of expansion of the lipid analyses to include many more samples than previously practical or possible. Large-scale study of lipids and surveying of the entire lipidome of an organism is now possible. Quantification of the change of several metabolite concentrations relative to the concentration change of one selected metabolite can reveal the site of action, in the metabolic network, of a 'silent gene'. Because of the easy access and a near universal contact with other tissues, blood plasma has long been known as a source of information about the metabolic state of the body. It is therefore no wonder that recent efforts of surveying the lipid metabolome have become centered on blood plasma. In a more limited but more specific way, the lipid metabolites present in other body fluids may also become of interest.

## Selected Applications

In the following, reference is being made to modern analyses of both major and minor lipids in selected biofluids, which may serve as examples for analyses of other internal and external secretions of animal bodies. Since many of the body fluids are exudates of plasma, the improvements in plasma lipid analyses are discussed in the greatest detail.

### Blood Cells, Plasma, and Plasma Lipoproteins

Detailed analysis of phospholipids, as well as neutral lipids and nonesterified fatty acids, has become progressively more important as these molecules have come to represent intercellular messenger molecules that are involved in a number of disease states. The analysis of lipid patterns of blood and lipoproteins may therefore constitute a useful diagnostic tool. As noted in the previous edition, suitable methods for phospholipid analysis are often time consuming and tedious, since most of them include several separation and derivatization steps.

**Phospholipids** The laborious combinations of thin-layer or liquid chromatography (LC) with gas chromatography (GC) for the analysis of phospholipids in biological fluids have been replaced by combinations of HPLC with MS (LC–MS). In many instances, the convenience of MS/MS mode of mass spectrometric identification of the erythrocyte and platelet phospholipids has been preferred to the LC–MS combination. A collision-induced dissociation of specific parent ions allows the deconvolution of the composition of the common mixtures of molecular species. For more complex phospholipid mixtures, a combined LC–MS approach is recommended.

Both lipid class and molecular species composition of glucosylated and nonglucosylated LDL phospholipids can be determined by a combination of normal-phase HPLC with online electrospray MS. **Figure 1** illustrates the normal-phase LC–MS resolution and identification of the major molecular species of the glucosylated ethanolamine phospholipids of LDL in the negative ion mode, while **Table 1** gives the relative proportions of the glucosylated and nonglucosylated phospholipid species. The glucosylation of the ethanolamine phospholipids of LDL was largely indiscriminate; both phosphatidylethanolamine (PtdEtn) and alkenylacyl GroPEtn components were glucosylated.

Schiller and Arnold have reviewed the analysis of phospholipids in HDL and LDL by MALDI time-of-flight-MS (MALDI-TOF-MS) and have compared the results with the data obtained by high-resolution  $^{31}\text{P}$  NMR spectroscopy. Differences between LDL and

HDL in sphingomyelin (SM) and phosphatidylcholine (PtdCho) content could be monitored by NMR and MS, and differences with respect to the extraction efficiency were found by MALDI-TOF-MS. Although MALDI-TOF-MS provided a reliable separation and reproducible lipid profile, only limited information was obtained on fatty acid composition.

LysoPtdCho can be determined by MALDI-TOF-MS and this technique is suitable for monitoring the digestion of PtdCho by pancreatic phospholipase  $\text{A}_2$ . The lysoPtdCho was quantified in relation to an internal standard of known concentration and by signal-to-noise ratios. All classes of lysophospholipids could be easily and sensitively analyzed by MALDI-TOF-MS. The smallest detectable amount of lysophospholipids was 0.09 pmol. This is about two orders of magnitude lower than the amount detectable by standard chromatographic methods. Earlier workers had used a simple and sensitive radioenzymatic assay for lysoPtdOH quantification. For this purpose, a recombinant rat lysoPtdOH acyl transferase (LPAAT) produced by *Escherichia coli* was used. In the presence of [ $^{14}\text{C}$ ]oleoyl-CoA, LPAAT selectively catalyzes the transformation of lysoPtdOH and alkyl-lysoPtdOH into [ $^{14}\text{C}$ ]PtdOH. Acylation of lysoPtdOH was complete and linear from 0 to 200 pmol with a minimal detection of 0.2 pmol. The method was used to quantify lysoPtdOH in lipids from bovine sera, as well as from human and mouse plasma. Cesium chloride (CsCl) had earlier been proposed as an auxiliary reagent for the analysis of PtdCho mixtures by MALDI-TOF-MS. In biological samples various cations are present (mainly  $\text{H}^+$ ,  $\text{Na}^+$ , and  $\text{K}^+$ ) and, therefore, a mixture of different adducts is formed. Since phospholipids exhibit a wide distribution of different fatty acid residues a considerable peak overlap may occur. This problem can be overcome by mixing the analyte with CsCl, which yields naturally nonoccurring  $\text{Cs}^+$  adducts that are apparent due to the large shift of the molecular mass.

Plasma lysophospholipids of diagnostic significance can be determined by electrospray ionization (ESI) MS. LysoPtdOH, lysoPtdIns, lysoPtdSer, and lysoPtdCho were detected at high sensitivity (in low picomole range) by this approach. The major ions and their identities were 409 (16:0-lysoPtdOH), 433–437 (18:2-, 18:1-, and 18:0-lysoPtdOH), 457 41–482 571 (16:0-lysoPtdIns), 599 (18:0 lysoPtdIns), and 619 (20:4-lysoPtdIns). Patients with either ovarian or peritoneal cancer have higher levels of both lysoPtdOH and lysoPtdIns compared with healthy controls: 457 (20:4-lysoPtdOH?), 481–482 (22:6-lysoPtdOH?), 571 (16:0 lysoPtdIns), etc.

**Figure 1** LC/ESI-MS analysis of oxidized PtdCho in oxidized LDL. Total positive ion current profile of oxidized LDL; (A) single ion plots of representative PtdCho oxidation products. Peak identification is as given in figure. LDL was oxidized by incubation with  $5 \mu\text{mol l}^{-1}$   $\text{CiSO}_4$  in  $0.1 \text{ mol l}^{-1}$  phosphate buffered saline (PBS) for 12 h at  $37^\circ\text{C}$ . The total lipid extract of the oxidized LDL was dissolved in chloroform/methanol (2:1, v/v) and  $20 \mu\text{l}$  of the sample containing  $10 \mu\text{g}$  lipid was analyzed. Structural assignment for aldehydes and hydroperoxides are according to reference standards. Ions 832 and 830 were identified on the basis of retention time and molecular weight. Analyses of lysophospholipids, including lysoPtdOH, lysoPtdIns, lysoPtdCho, lysoPtdSer, sphingosine-1-phosphate, and sphingosine phosphorylcholine in human body fluids from subjects with different pathophysiological conditions, revealed not only the relevance of lysophospholipids in human disease, but also their potential application as biomarkers and/or therapeutic targets. These compounds are detected by a variety of methods, no single method is available.

The oxidation products of plasma and lipoprotein phospholipids have been the subject of extensive study by chromatographic and mass spectrometric methods. Earlier, workers had reported the simultaneous determination of phospholipid hydroperoxides and cholesteryl ester hydroperoxides in human plasma by HPLC with chemiluminescence monitoring. Lipid hydroperoxides were quantitatively extracted from human plasma with a mixture of *n*-hexane and

ethyl acetate, and separated by column-switching HPLC using one aminopropyl column and two octyl columns followed by chemiluminescence detection. More specific identification of the hydroperoxides and isoprostanes in plasma phospholipids are obtained by GC coupled with MS (GC–MS), as described for urine and other body fluids (see below). **Figure 2** shows the total ion current profile and the characteristic single ion chromatograms representing the major core aldehyde, hydroperoxide, and isoprostane-containing PtdChos.

<sup>31</sup>P NMR studies of lipoprotein subfractions were first performed in the early 1970s and were dedicated to the investigation of the structure and motion of phospholipids in human plasma lipoproteins. In the 1990s, it was shown that <sup>31</sup>P NMR investigations of blood and of isolated lipoprotein subfractions gave results that agreed well in accuracy and reproducibility with data obtained by enzymatic and TLC methods. <sup>31</sup>P NMR spectroscopic characterization of erythrocyte phospholipids is a well-established technique. Both one- and two-dimensional NMR spectroscopy have been applied to determine quantitatively the lipids extracted from human erythrocyte membranes. The molecular species of the phospholipids were determined after a HPLC fractionation of the lipid extracts and NMR analysis of each lipid class. The results of proton NMR analysis show good agreement with classical lipid analytical techniques. **Figure 3** shows <sup>31</sup>P NMR spectrum of sodium cholate-treated human hemolysate. It is evident that several resonances can be assigned to the various phospholipid classes in human erythrocytes, whereas these resonances are totally absent in the relevant section of the <sup>31</sup>P NMR spectrum of untreated human erythrocytes. <sup>31</sup>P NMR spectroscopy is a convenient and precise analytical tool for the phospholipid analysis of extracts from biological samples of body fluids. Because of its limited sensitivity, <sup>31</sup>P NMR spectroscopy is best suited for work with lipid-rich body fluids. Thus, <sup>31</sup>P NMR spectroscopy has been applied to human blood to monitor chemotherapy-associated changes of serum phospholipids in patients with malignant lymphomas. During therapy leading to remission of cancer, resonances of phospholipids increased progressively, resulting in spectra similar to those seen in the normal sera. The spectral resolution is not high enough to identify molecular species of glycerophospholipids.

**Cholesterol, plant sterols, and bile acids** Measurements of cholesterol and plant sterols in plasma and lymph are obtained by GC, but HPLC has also gained in importance as a method of sensitive

**Figure 2** LC/ESI-MS analysis of oxidized PtdCho in oxidized Glc-PtdEtn LDL. 5  $\mu\text{l}$  plasma samples and 3 mm blood spots are quantified using deuterium-labeled internal standards. Patients with peroxisomal disorders, who lack the ability to chain-shorten the  $\text{C}_{27}$  bile acid

intermediates into  $\text{C}_{24}$  bile acids, have elevated levels of  $\text{C}_{27}$  bile acids. **Figure 4** shows the ESI-MS/MS analysis of the acetyl dimethylaminoethyl esters extracted from 3 mm dried blood spots. The neutral loss of 60 Da scan for a control blood spot and for a blood spot from a patient is characteristic of a peroxisome biogenesis defect. The reversed-phase LC-ESI-MS method is also used for the analysis of conjugated bile acids.

**Antioxidant levels** HPLC is a well-suited technique for the determination of tocopherols, tocotrienols, ubiquinols, and ubiquinones in biological samples. An automated method for the determination of the total antioxidant capacity (TAC) of human plasma, based on the crocin bleaching assay, is now widely used. The TAC method shows good agreement with the total antioxidant status (TAS) test. Reference value derived from samples of normal blood donors was  $1.175 \pm 0.007 \text{ mmol l}^{-1}$ , while a diet rich in antioxidants more than doubled this value. **Table 3** illustrates the plasma carotenoid and fat-soluble vitamin concentrations of men and women consuming plant steryl esters. There were significant decreases in  $\beta$ -carotene,  $\alpha$ -carotene, and  $\beta$ -cryptoxanthin (females only) not associated with changes

**Figure 4** ESI-MS/MS analysis of the acetyl dimethylaminoethyl esters extracted from 3 mm dried blood spots. A neutral loss of 60 Da scan is shown for (A) a control blood spot, and (B) a blood spot from a patient with peroxisome biogenesis defect (Zellweger syndrome variant). The x-axis shows the molecular weights of the protonated molecular ions that lose acetic acid. in plasma lipids. Total plasma carotenoids decreased 9.6% with plant steryl ester consumption.

### Lymph

High-temperature GLC profiles of polyunsaturated triacylglycerols are greatly improved by hydrogenation, resulting in a higher recovery of the long-chain species. Lymph lipids can be analyzed by reversed-phase HPLC using evaporative light scattering detection to quantify the lymph triacylglycerols. The triacylglycerols are identified by atmospheric pressure chemical ionization MS. **Figure 5** shows the total ion current chromatogram of lymph triacylglycerols 2 h after administration of various structured triacylglycerols. The triacylglycerols are identified by their ammonium adduct molecular ions and diacylglycerol fragment ions, and by the relative intensity of the fragment ions.

### Milk

No single method or combination of methods is adequate to prepare fatty acid methyl esters (FAME)

from all classes of milk or rumen lipids, which does not simultaneously affect the conjugated dienes. The availability of long polar capillary columns (50–100 m) for GC has improved the resolution of many positional and geometric fatty acid isomers. Prior separations with argentation chromatography, however, still show several regions with overlapping peaks, especially in the mono- and diunsaturated fatty acid region. **Figure 6** shows a typical GC separation of total bovine milk FAMES prepared by NaOCH<sub>3</sub>/methanol followed by HCl/methanol, and separated on a 100 m fused silica capillary column. **Figure 7** shows the expanded methyl eicosanoate to methyl arachidonate region of the GC of total bovine FAMES.

### Urine

Oxidant stress has been widely implicated as a mechanism of disease, but clinical trials of antioxidants have failed to include a biochemical basis for dose selection or patient inclusion. Commonly employed *in vivo* indices of lipid peroxidation are constrained

**Table 3** Plasma carotenoid and fat-soluble vitamin concentrations of men and women consuming plant steryl esters ( $3.6 \text{ g day}^{-1}$ )

Carotenoids and fat-soluble vitamins	<i>LSMean</i> $\pm$ <i>SEE</i> <sup>a</sup>	
	Control	Plant steryl esters
Total carotenoids <sup>b</sup>	116 $\pm$ 2.7	105 $\pm$ 2.7

by such issues as the nonspecificity or instability of the target analyte, contamination of the analyte by events *ex vivo*, and nonspecificity of analytical methodology. Specific methodology based on MS applied to both 4-hydroxynonenal and a variety of isoprostanes in human biological fluids, and urinary isoprostanes, resulted in their selection as potential markers of oxidant stress in atherothrombotic disease.

Thus, enhanced urinary excretion of 8-isoprostaglandin  $F_{2x}$  (8-iso-PGF $_{2x}$ ) has been associated with cardiac reperfusion injury and with cardiovascular risk factors, including cigarette smoking, diabetes mellitus, and hypercholesterolemia. The determination of human urinary iso-PGF $_{2x}$  type III by GC–electron impact MS (GC–EI–MS) has been compared to enzymatic assays. The results of GC–EI–MS did not agree with those determined by the enzyme immunoassay and it was apparent that the two methods did not measure the same compounds. An improved assay for the quantification of the major urinary metabolite of the isoprostane 15-F(2t)-8-iso-PGF $_{2x}$  has been proposed using stable isotope dilution GC–MS with negative ion chemical ionization. This assay provides a sensitive and accurate method to assess endogenous isoprostane generation and can be used to further explore the role of oxidant injury in human disease. Evaluation of the isoprostane levels in plasma and urine in type 2 diabetic patients,

**Figure 5** Total ion current chromatogram of acylglycerols 2 h after administration of structured triacylglycerols (A) 1,3-dioctanoyl-2-linoleoyl-*sn*-glycerol (8:0/18:2/8:0), (B) 1,3-didecanoyl-2-linoleoyl-*sn*-glycerol (10:0/18:2/10:0), and (C) 1,3-didodecanoyl-2-linoleoyl-*sn*-glycerol (12:0/18:2/12:0), and of safflower oil (D). and comparison to other currently used biomarkers of oxidative stress, has indicated that the measurement of same oxidative stress biomarker, isoprostane, in two different biological fluids, plasma and urine, leads to divergent results. Therefore, it is important to measure a biomarker both in circulation fluid (plasma) and in the elimination fluid (urine) to have a general idea of what is occurring in the organism.

### Bronchoalveolar Lavage

Bronchoalveolar Lavage (BAL) fluid covers the alveolae of the lungs as a thin film. The bulk of the BAL lipids are phospholipids with a very high proportion of palmitic acid.  $^{31}\text{P}$  NMR has shown that besides the dipalmitoyl glycerophosphocholine (GroPCho) and glycerophosphoglycerol (GroPGro), minor lipid classes such as plasmalogens are also present and can be quantified. Organic solvent extracts of BAL from different animal species in combination with MALDI-TOF-MS is a very good

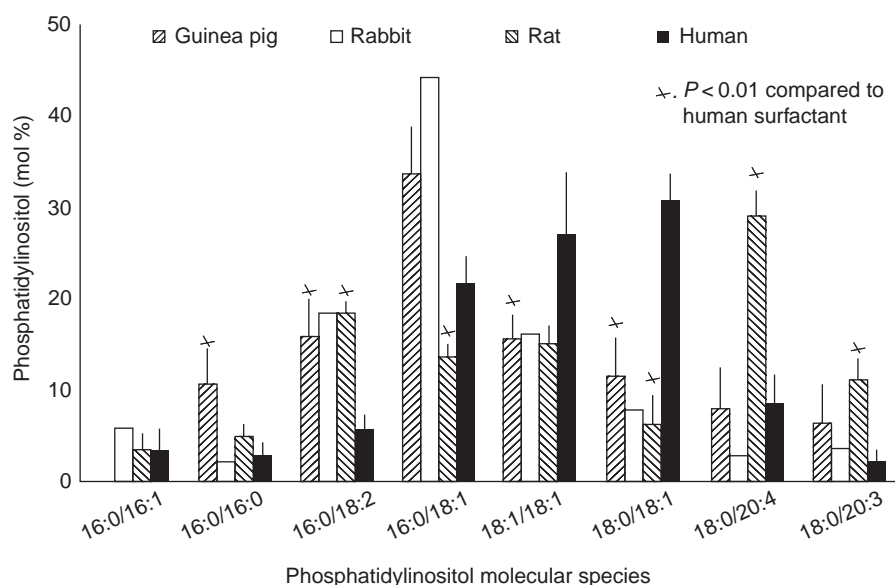

**Figure 6** A typical gas-liquid chromatogram of total bovine milk FAME prepared by  $\text{NaOCH}_3$ /methanol (10 min at  $50^\circ\text{C}$ ) followed by  $\text{HCl}$ /methanol (10 min at  $80^\circ\text{C}$ ), and separated on a 100 m fused silica capillary column (SP-2560; Supelco Inc., Bellefonte, PA). I, iso; a, anteiso; numbers 1–20 are arbitrary consecutive numbering of all peaks in the region between 18:0 and 18:2n-6 using this column. (22:6n-3) is not present in these milk samples but the position at which it should emerge in the chromatogram is indicated. Insert the methyl eicosanoate (20:0) to methyl arachidonate (20:4n-6) region of the GLC of total bovine fatty acid methyl esters prepared by using conventional catalysts. Reproduced with permission from Kramer JKG, Fellner V, Dugan MER, Sauer FD, Mossoba MM, and Yurawecz MP (1997) *Lipids* 32: 1219–1228.

**Figure 7** The methyl eicosanoate (20:0) to methyl arachidonate (20:4n-6) region of the GLC of total bovine fatty acid methyl esters prepared by using the following catalysts in anhydrous methanol: (A)  $\text{NaOCH}_3$ ; (B)  $\text{HCl}$ ; (C) acetyl chloride; or (D)  $\text{BF}_3$ . Other analytical conditions as in **Figure 6**. The fatty acids are identified by reference to both methyl terminal ( $n$  system) and carboxyl terminal ( $\Delta$  system). **Figure 8** The composition of individual molecular species of phosphatidylinositol in mammalian surfactants as determined by mass spectrometry. Reproduced with permission from Postle AD, Heeley EL, and Wilton DC (2001) *Comparative Biochemical Physiology, Part A* 129: 65–73.

method for the identification of the phospholipid classes along with the molecular species composition. Both  $^{31}\text{P}$  NMR and MALDI-TOF-MS provided fast and reliable information on the lipid composition of the BAL. However, despite of its comparable insensitivity  $^{31}\text{P}$  NMR spectroscopy detected all phospholipid classes in a single experiment and with the same sensitivity, whereas MALDI-TOF-MS failed in the detection of PtdEtn in the presence of higher quantities of PtdCho. While the BAL of all humans contains dipalmitoyl GroPCho, the composition of BAL differs from animal to animal. **Figure 8** shows the composition of the molecular species of phosphatidylinositol (PtdIns), which is a minor component of mammalian surfactants. Many others have measured platelet activation factor (PAF)-like compounds in BAL. Hyperoxia increased the concentration of PAF-like compounds, lipid hydroperoxides, and malondialdehyde in plasma but not in BAL. **Table 4** lists the phospholipids identified by ESI and ESI-MS/MS in Cursurf®, a natural pulmonary surfactant. Cursurf® contains low molecular weight hydrophobic apoproteins and a series of phospholipids. It is used in the treatment or prophylaxis of neonatal respiratory distress syndrome, associated with limited capacity of surfactant production in premature newborns.

### Amniotic Fluids

Using a solvent-reagent system gives narrow line-widths in  $^{32}\text{P}$  NMR spectra of phospholipid extracts when applied to human amniotic fluid. Resolution of the major components is achieved by manipulating

the solvent composition, and assignments can be made by spiking samples with standard compounds. Specifically, estimates of PtdCho/SM ratio and phosphatidylglycerol (PtdGro) and PtdIns were obtained by high-resolution of  $^{31}\text{P}$  NMR.

### Cerebrospinal Fluid

Koch *et al.* determined total cholesterol, phospholipids, and fatty acids in CSF samples from 216 individuals in order to establish the lipid and apolipoprotein levels in Cerebrospinal Fluid (CSF) in a large group of individuals, on the basis of which a classification of CSF lipoproteins was made. The cholesterol and phospholipids are measured enzymatically by fluorometric detection of the reaction products. Earlier work had shown reduced levels of cholesterol, phospholipids, and free fatty acids in Cerebrospinal Fluid (CSF) of Alzheimer disease patients. Urine levels of  $\text{F}_2$ -isoprostanes or their major metabolite were not significantly different between Alzheimer's disease patients and controls. In addition, urine and CSF  $\text{F}_2$ -isoprostanate levels in Alzheimer's disease patients did not correlate. These results indicate that plasma and urine  $\text{F}_2$ -isoprostanes and  $\text{F}_2$ -neuroprostanes do not accurately reflect central nervous system levels of these biomarkers and are not reproducibly elevated in body fluids outside of the central nervous system in Alzheimer's disease patients.

The choline and ethanolamine containing phospholipids yielded Na<sup>+</sup> adducts (plus 23 u); in the negative ion mode, the choline containing phospholipids gave Cl<sup>−</sup> adducts (plus 35 and 37 u). Reproduced with permission in a modified form from Pelizzi N, Catinelli S, Barbosa S, and Zanol M (2002) *Rapid Communications in Mass Spectrometry* 16: 2215–2220.

account for 96–99% of total salivary lipids. The salivary lipids do not float on centrifugation like blood plasma lipids and appear to exist in a different state of aggregation from lipids in blood and lymph. The analyses were performed by TLC using both neutral and polar solvents. The lipids were located by charring and the lipid spots quantified by scanning densitometry at 350 nm.

## Introduction

The classical methods of recrystallization and distillation fail to provide isolation and proper

purification of more than simple mixtures. Chromatography is a more efficient method in this respect. Any chromatographic system consists of three components: a stationary phase, a mobile phase, and the sample. Liquid chromatography (LC) operates with a liquid mobile phase as opposed to gas chromatography (GC). LC is widely used to follow the course of reactions, to separate complex mixtures, to establish the presence and quantity of specific compounds in physiological materials, etc. Thus, this chromatographic method is daily applied in

laboratories such as in analytical chemistry, organic synthesis, biochemistry, medicine, and ecology and in production processes in industry. This article deals briefly with the history, importance, and different classifications of LC. Moreover, the parameters connected with the retention and separation of analytes are discussed along with the correlations among them. These parameters are related to the structure of analytes and the chromatographic conditions used. Their adjustment is crucial for obtaining good or optimum separation.

## LC versus GC

In 1903, a botanist Mikhail Tswett achieved unexpectedly the separation of chlorophyll and xanthophylls into their components. In the method he used, a petroleum ether solution of any of these mixtures is passed through calcium carbonate placed in a glass tube (column). This new separation method was called 'Chromatography'; i.e. 'colored writing', owing to the development of separated colored zones within the length of the column. Any of these zones corresponds to a specific component. This experiment is the beginning of both chromatography and LC. In this case, calcium carbonate was the solid stationary phase and petroleum ether (a mixture of hydrocarbons) is the liquid mobile phase. Since then, column liquid-solid chromatography (LSC) has been widely used. In the case of column chromatography (CC), the stationary phase is a three-dimensional bed. The column contains the stationary phase and the analyte. The mobile phase is added at the top of the column under atmospheric pressure. Its movement results in different retention of the analyte components according to their structure.

The development of LC was rapid with the appearance of several different methods and techniques. Some trends are outlined. Liquid-liquid chromatography (LLC) was introduced in 1941. In this case, both the stationary phase and mobile phase are immiscible liquids. The stationary phase is a porous material (support) covered with a thin film of liquid. A variation of LLC is paper chromatography (PC), where the stationary phase is paper with the water included in its pores. PC was the first planar technique. The term 'planar' comes from the fact that the stationary phase (paper) is a two-dimensional bed. A subsequent planar technique is thin-layer chromatography (TLC). In this case, the stationary phase is a thin layer of solid material, composed of small particles, spread on a glass plate or an aluminum sheet.

High-performance liquid chromatography (HPLC) is the modern version of CC.

GC requires elevated temperatures. It is an indispensable method for the separation of volatile organic compounds that do not decompose at higher temperatures.

LC is usually performed at room temperature. Thus, it is suitable for analysis of all kinds of compounds: organic and inorganic compounds, compounds of low and high molecular mass, and labile compounds such as explosives and stable compounds. The conventional CC and planar techniques do not require the use of expensive instruments. HPLC competes with GC in precision and effectiveness. However, the reproducibility is usually lower. If necessary, a high reproducibility is obtained with more precautions.

## Interaction of Analyte with Both Phases

Let us consider that the analyte is composed of one compound. The analyte interacts in a specific way with both the stationary phase (s) and the mobile phase (m). The interactions are usually weak (solvation, adsorption, etc.) without formation of chemical bonds. An electrostatic interaction occurs in specific cases only. According to its structure, an analyte X interacts better with the stationary phase by sorption or mobile phase by desorption. Equilibrium processes between (1) the analyte and stationary phase and (2) the analyte and mobile phase take place. These processes are represented in a simpler way by a single equilibrium process:

Within this equilibrium, the molecules of X are sorbed and desorbed and thus move to some extent with the flow of the mobile phase. The equilibrium is characterized by a distribution coefficient  $K_D$ :

$$K_D = \frac{[X]_s}{[X]_m} \quad [2]$$

where  $[X]$  is the molar concentration of compound X in the corresponding phase. Thus,  $K_D$  is a measure of the retention of X in the chromatographic system. The greater  $K_D$  is, the greater the retention of X and vice versa. The plot of  $[X]_s$  versus  $[X]_m$  is called a sorption isotherm. Its shape is different, but usually there is some part that is linear. Performance of LC in this part of the isotherm is most effective. The capacity, and thus efficiency, of a chromatographic system depends on the ratio of the masses of the analyte and the stationary phase. If the quantity of the analyte is greater, the chromatographic system is

overloaded and operates, with a decreased efficiency, in the nonlinear part of the isotherm.

## Mechanisms of Interaction

Depending on the chromatographic system, the analyte interacts in a different way or through a different mechanism with the stationary phase and mobile phase. Four main mechanisms of interactions are known for LC.

**Partition mechanism:** It concerns partition between two immiscible liquids. The analyte has different solubility in each phase. If it is better dissolved in the stationary phase than in the mobile phase, its  $K_D$  is greater (Figure 1A).

**Adsorption mechanism:** The stationary phase contains, on its surface, active sites, and the analyte adsorbs on them (Figure 1B). The mobile phase tries to desorb them.  $K_D$  is greater if adsorption dominates over desorption.

**Ion-exchange mechanism:** The stationary phase contains, on its surface, ions (cations or anions), and the analyte exchanges its own ions with the counterions of the stationary phase. Figure 1C shows an example of separation using an anion exchanger. Such an analyte has a greater  $K_D$  than does a compound where such an exchange is not possible.

**Size-exclusion mechanism:** The stationary phase is a solid material composed of porous particles with specific inner pore diameters. An analyte with smaller size goes into the pores and has a greater  $K_D$ . An analyte larger than the pores moves with the mobile phase outside the porous particles and has a smaller  $K_D$  (Figure 1D).

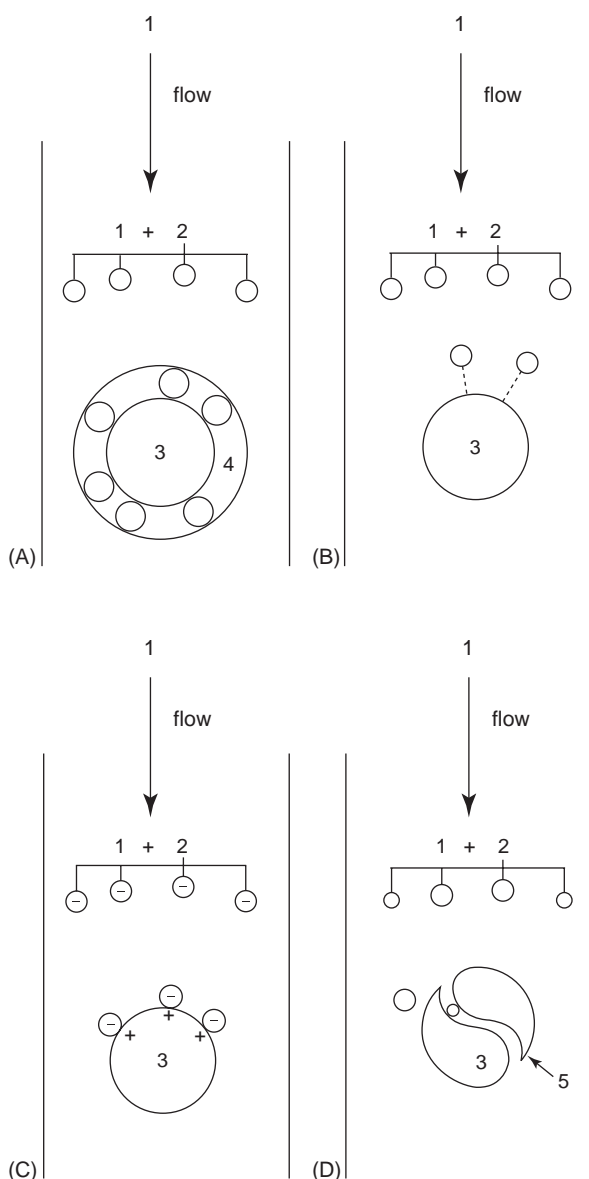

**Other mechanisms:** Affinity and ion-pair LC are based on modifications of the adsorption mechanism and ion-exchange mechanism, respectively.

## Classifications of Liquid Chromatography

LC involves various methods and techniques. This requires its classification from different points of view.

### Classification by the Physical State of Phases

The mobile phase is always liquid. The stationary phase is liquid or solid. Table 1 shows in detail this classification. There are two modifications of LSC: normal phase (NP) and reversed-phase (RP), depending on the relative polarity of the two phases. The same is valid for LLC, but this subdivision is rarely

**Figure 1** Retention mechanisms in LC: (A) partition; (B) adsorption; (C) ion-exchange; and (D) size-exclusion. 1, liquid mobile phase; 2, sample molecules or ions, shown as circles (the latter and '2' are connected by lines); 3, stationary phase (one particle; in case (A), 3 is a support particle covered with thin film of liquid, 4 being the stationary phase itself); 5, an inner pore in a stationary phase particle 3.

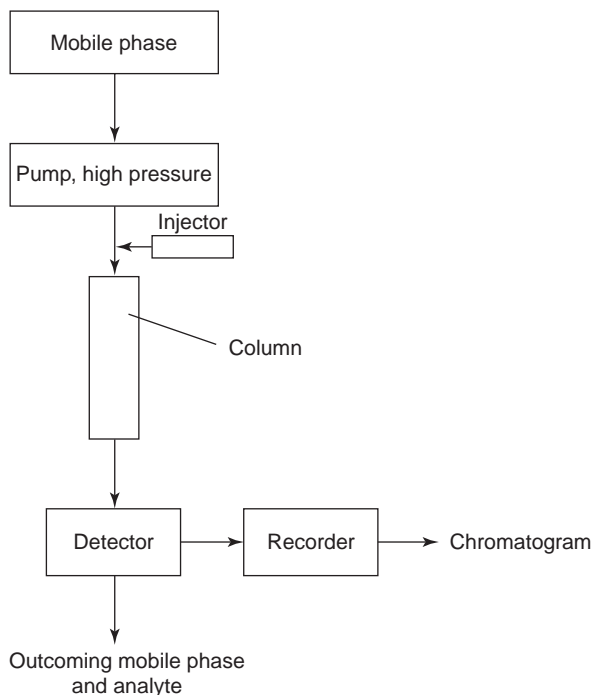

pointed. Methods 1, 2a, and 2b are of general applicability. Methods 3 and 4 apply in specific cases. Method 1 is suitable for separation of organic and inorganic ionic compounds. Methods 2a and 2b are indispensable and widely applied for analysis of nonionic organic compounds. Method 2a is better for separation of isomers including stereoisomers. A modification of LSC is supercritical fluid chromatography, where the mobile phase is a supercritical fluid.

**Table 1** Classification and mechanisms of LC methods

No.	Method	Stationary phase	Main sorption mechanism
1	LLC	Thin film of liquid (on solid)	Partition between two immiscible liquids
2	LSC	Solid	
2a	NP LC	Polar solid	Adsorption
2b	RP LC	Nonpolar solid	Adsorption
3	Ion-exchange chromatography	Ion-exchange resin	Ion-exchange
4	Size-exclusion chromatography	Solid	Sieving

### Classification by the Bed of the Stationary Phase

CC, three-dimensional bed. Conventional CC is performed at atmospheric pressure. The stationary phase particles are large compared with HPLC: the particle diameter ( $d_p$ ) is usually in the range 60–200  $\mu\text{m}$ . Thus, atmospheric pressure is sufficient to overcome the flow resistance of the packed column. This ensures a normal flow rate ( $1\text{--}3\text{ ml min}^{-1}$ ) of the mobile phase. HPLC runs at the higher pressure necessary to overcome the resistance of the smaller particles (usually with  $d_p\ 5\ \mu\text{m}$ ) of the stationary phase. A normal flow rate of the mobile phase is obtained at a pressure of 10–20 MPa. The high efficiency in HPLC is due to the small and uniform size of particles. **Figures 2** and **3** illustrate the equipment necessary for performing conventional CC and HPLC, respectively. In the first case, a unique instrument (chromatograph) is not used. The analyte is applied to the top of a glass column containing the stationary phase. The mobile phase, called the eluent, passes through the column, and this leads to separation of the solute into its components. The outcoming solvent (eluate) from the column is collected in separate fractions, and the compositions are followed using another method. In the case of HPLC, a chromatograph is used. It is composed of six parts: (1) a mobile-phase delivery vessel(s), (2) a pump for producing a high pressure, (3) an injector for application of the analyte, (4) a column containing the stationary phase, (5) a detector (usually UV) giving signals for the composition of the mobile phase exiting from the column, and (6) a data station and data processing unit: the record of the separation is called a chromatogram. The latter is composed of peak(s): any peak corresponds to a specific compound if a complete separation is achieved (**Figure 4**).

**Figure 2** Schematic representation of conventional CC.**Figure 3** Schematic representation of the components of HPLC.

**Figure 4** HPLC chromatogram of a compound.

### Classification by the Composition of the Mobile Phase

To tune the retention of the vast number of known compounds, the mobile phase in LC is usually a mixture of two or more solvents.

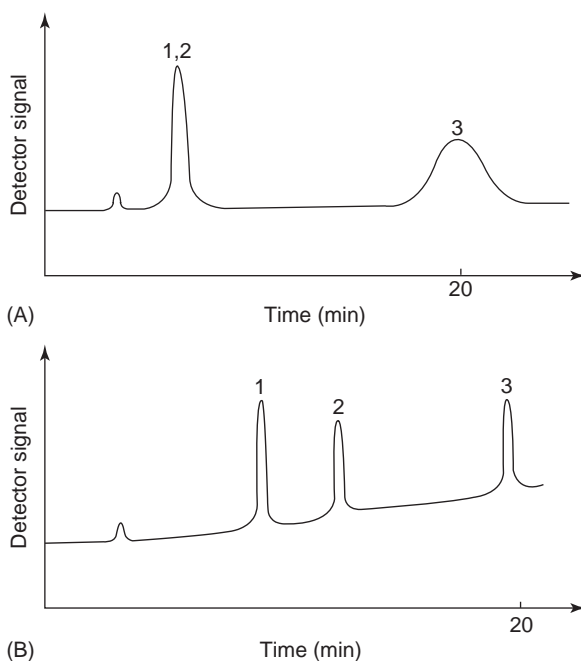

**Isocratic technique.** In this technique, the mobile phase has a constant composition, for example acetonitrile–water 72:28.

**Gradient technique.** In this case, the composition of the mobile phase varies in a specific way, resulting in better separation. It is especially useful if there is a greater difference in the retention of analyte components. It reduces the peak broadening especially for compounds with greater retention times (**Figure 5**). For instance, the gradient change of the mobile-phase composition can be expressed in the following way: mobile phase A = hexane–ethyl acetate 70:30, mobile phase B = hexane–ethyl acetate 30:70, linear gradient from A to B in 16 min.

### Classification by the Analyte Quantity

**Analytical technique.** The quantity of the analyte is small (usually a few micrograms). This chromatographic technique gives an analysis of the analyte composition.

**Preparative technique.** The quantity of the analyte is greater (usually  $\sim 0.5$ –1 g). Thus, the individual components of the analyte are isolated in some quantity. Conventional column LC operates in this mode only. The ratio between the mass of the analyte and stationary phase, i.e., the column capacity, varies usually from 1:50 to 1:100. Chromatographic filtration is a technique where this ratio is smaller, for instance 1:20. It is applied when the analyte is composed of compounds with a greater difference in retention. The efficiency of conventional CC is improved by an increase in pressure (1.2–1.5 atm.) over

**Figure 5** Comparison between (A) isocratic technique and (B) gradient technique.

the column when the stationary phase has smaller particles ( $d_p$  40–60  $\mu\text{m}$ ). To this end, the column is connected with a bottle of liquid nitrogen or helium. This technique is called low-pressure CC or flash chromatography.

HPLC and TLC operate in both modes. In the case of preparative TLC, thick layers of the stationary phase are used.

### Classification by the Possibility of Structural Determination

LC itself does not give the possibility of determining the structure of the individual analyte components in the course of their separation. However, the combination of LC with a specific spectral method enables such a determination. In such a case, after the detector, the mobile phase passes online through the relevant spectrometer. The spectrometer records the spectrum of any peak. LC–mass spectrometry and LC–infrared spectrometry are the most popular techniques. LC–nuclear magnetic resonance spectrometry is becoming increasingly important. If such instruments are not available, structural determination is performed in the classic way. This requires quantitative separation of the analyte and isolation of the individual components in milligram quantities. Spectroscopic instruments that are not connected with the chromatographic system are used to elucidate the structure of the separated compounds.

### Miscellaneous Methods or Techniques

Modification of the mobile phase or the stationary phase leads to new methods or techniques. For instance, inclusion of silver ions from silver nitrate mainly in the stationary phase is used in argentation LC. This method enables a better separation of analytes containing one or more double bonds. The double bond forms a complex with the silver ion and this complex has greater retention, giving the possibility of differentiating the retention of compounds with double bond(s). Modification of the stationary phase with chiral compounds enables separation of the chiral compounds, which are of primary importance nowadays. This technique is called chiral separation.

### Chromatographic Parameters Characterizing Analyte Retention

The distribution coefficient,  $K_D$ , is difficult to determine from the chromatogram. Thus, other chromatographic parameters are defined to characterize the analyte retention directly from the chromatogram.

In the case of HPLC, the retention volume ( $V_R$ ) and retention time ( $t_R$ ) of a compound are equal to the volume of the mobile phase and the time passed until its peak appears in the chromatogram, respectively (see Figure 4). These two parameters are not constant. Their values depend on the column type being characterized by the parameters  $V_o$  (breakthrough or dead volume) and the corresponding time,  $t_o$  (breakthrough or dead time), for an unretained compound. The retention factor,  $k$ , as defined in eqn [3], is a constant measuring the retention.

$$k = \frac{t_R - t_o}{t_o} \quad \text{or} \quad k = \frac{V_R - V_o}{V_o} \quad [3]$$

The greater  $k$  is, the stronger the retention of the compound.

In the case of planar chromatography, the first defined parameter is  $R_F$ :

$$R_F = \frac{S}{S_o} \quad [4]$$

where  $S$  and  $S_o$  are the distances from the start line to the center of the zone and to the front line, respectively. This parameter measures, in fact, the mobility of the analyte since the greater  $R_F$  is, the smaller the analyte retention. The retention factor in TLC,  $R_M$ , is related to  $k$  and  $R_F$ :

$$R_M = \log k = \log \left( \frac{1}{R_F} - 1 \right) \quad [5]$$

In the case of conventional CC, the retention is approximately measured by  $V_R$ . This technique is preparative; the chromatographic system is overloaded by the analyte and thus  $V_R$  varies from separation to separation.

### Chromatographic Parameters Characterizing Analyte Separation

Let us assume that the analyte is composed of two or more compounds. The main goal in LC is to separate a pair of compounds.

Referring to compounds 1 and 2 analyzed under same conditions, the separation factor,  $\alpha$ , is defined in the following way:

$$\alpha = \frac{k_2}{k_1} \quad \text{or} \quad \log \alpha = \log k_2 - \log k_1 = R_{M(2)} - R_{M(1)} \quad [6]$$

where the subscript specifies the compound. The greater  $\alpha$  is, the better is the separation. No separation is achieved if  $\alpha = 0$  or  $\log \alpha = 1$ . Parameter  $\alpha$  does not take into account the peak width or zone width. However, this factor is important since the wider the peaks are, the poorer the separation. The resolution,  $R$ , depends on the retention and peak width (Figure 6):

$$R = \frac{2[t_{R(2)} - t_{R(1)}]}{W_{(1)} + W_{(2)}} \quad [7]$$

where  $W$  is the width of the corresponding peak. In analogy with a fractionation column, the chromatographic system is considered to consist of a vast number of imaginary plates, called theoretical plates,  $N$ , being easily found from the HPLC chromatogram. The equilibrium between sorption and desorption is assumed complete within any theoretical plate.  $R$  is a function of  $N$ , the mean value of  $k$  for both compounds, and  $\alpha$ :

$$R = \frac{\sqrt{N}}{4} \left( \frac{\alpha - 1}{\alpha} \right) \left( \frac{k}{1 + k} \right) \quad [8]$$

**Figure 6** Parameters necessary for calculation of resolution,  $R$ , using eqn [7].

In LC, the value of  $N$  varies usually from 1000 to 10 000. This factor depends mainly on the stationary phase particle size and is the main reason for the better separation achieved by LC compared with distillation. The values of  $k$  and  $\alpha$  should adjust in such a way as to give a greater value of  $R$  for a reasonable analysis time. To this end, variation of the mobile phase composition and its flow rate,  $F$ , is of significant importance. According to eqn [8],  $R$  is greater at better separation,  $\alpha$ , and stronger retention (greater values of  $k$ ). Reasonable values of  $k$  fall in the range 1–20. Greater values of  $k$  require a longer analysis time, and this is an unfavorable factor. Moreover, the peaks at greater  $k$  become diffuse and asymmetric. This phenomenon is known as peak (band) broadening, being undesired in LC. It leads to partial separation or overlap of two or more peaks. Thus, the suitable conditions for performance of LC are a compromise of various factors.

As mentioned, the flow rate of the mobile phase in the chromatographic system is an important factor for its separation selectivity. It is connected with diffusion and mass transfer in the chromatographic system since LC is a dynamic process. A small flow rate results in greater retention times and strong peak broadening due to diffusion effects. A high flow rate leads to short retention times and peak broadening because the mass transfer between the stationary and mobile phases needs some time. Thus, an optimum flow rate is applied. It is established by the Van Deemter equation. The theoretical plate height,  $H$  (equal to the ratio of bed length,  $L$ , to  $N$ ), is expressed as a function of the linear velocity,  $u$ , of the mobile phase. The flow rate is a product of  $u$  (in  $\text{cm s}^{-1}$ ) and the column diameter. A recent modification of the Van Deemter

equation is

$$H = A + B/u + C_s \cdot u + C_m \cdot u \quad [9]$$

where  $A$  represents the flow anisotropy created by the lack of homogeneity of the column packing, the second term on the right side results from longitudinal diffusion, and the third term from mass transfer into and out of the stationary phase. A plot of  $H$  versus  $u$  gives a curve showing a minimum. The use of the linear velocity,  $u$  (and the relevant flow rate), corresponding to that minimum results in the best separation efficiency of the chromatographic system regarding diffusion and mass transfer.

## Introduction

The process in liquid chromatography (LC) is the result of the interaction among an analyte, a stationary phase, and a mobile phase. Moreover, LC is subdivided into liquid–liquid chromatography (LLC) and liquid–solid chromatography (LSC). Both methods are performed in normal-phase (NP) mode and reversed-phase (RP) mode depending on the relative

polarity of both phases. Two other methods are known: ion exchange and size exclusion. The chromatographic parameters  $k$ ,  $R_F$ ,  $R_M$ ,  $\alpha$ , and  $R$  measure retention of analytes and their separation. The relationships among these parameters are important to obtain good separation for reasonable analysis time. All methods are performed by the conventional column chromatography (CC), modern column chromatography, denoted as high-performance liquid chromatography (HPLC), or planar thin-layer chromatography (TLC).

This article deals with the essential theory of LC. Attention is paid to the stationary-phase types,

details of retention mechanisms, and theory of chromatographic process including some quantitative relationships. This knowledge is of importance for selection of a proper method and suitable conditions for a specific separation known as method development. Recommendations in this respect are given. Application of theory requires an understanding of operating principles of the techniques in LC.

## Main Stationary Phases

A stationary phase suitable for LC should meet various requirements such as to be: (1) incompressible, (2) insoluble in the mobile phase, and (3) does not interact with the analyte. Relatively few stationary phases meet these requirements and thus are widely used. They are briefly described. All of them are commercially available in different particle size, being almost uniform or varying in smaller or greater range. In general, the particle diameter in LC is from 1 to 200  $\mu\text{m}$ .

### Silica ( $\text{SiO}_2$ )

The active sites (centers) of silica are mainly the free and bonded silanol groups as shown in **Figure 1**. Two vicinal silanol groups connected by hydrogen bonds form the bonded hydroxyl groups. In the case of normal-phase liquid chromatography (NPLC), these sites interact with the polar analyte functional group/s. Thus, silica is considered as a polar stationary phase. The properties of a specific silica depend on its surface area and the number of active sites.

### Alumina ( $\text{Al}_2\text{O}_3$ )

The active sites of alumina are the aluminum cations ( $\text{Al}^{3+}$ ) and oxygen anions ( $\text{O}^{2-}$ ). Thus, this stationary phase is also polar.

Chemically bonded silica are available. Silica is especially useful in LC and modifications of its active sites are well known.

### Polar-Bonded Silica

These are spacer-bonded propanediol silica, amino-propylsiloxane-bonded silica, and cyanopropylsiloxane-bonded silica having on their surface, as active sites, hydroxyl (OH) groups, amino ( $\text{NH}_2$ ) groups, and cyano (CN) groups, respectively.

**Figure 1** Main active sites of silica: (A) free silanol group and (B) bounded silanol groups.

### Nonpolar-Bonded Silica

These silica have, as active sites, a siloxane-bonded alkyl group R instead of the silanol groups. There are various reactions leading to such a modification of silica. For example, the reaction of silica with a tri-alkylchlorosilane:

$\text{R}^1$  is usually octyl ( $\text{C}_8\text{H}_{17}$ ) or octadecyl ( $\text{C}_{18}\text{H}_{37}$ ) and is the active site in the case of reversed-phase liquid chromatography (RPLC). The notation RP-18 means that the stationary phase is a siloxane-bonded silica with octadecyl groups on its surface. This stationary phase is nonpolar and thus is suitable for RPLC.

The stationary phase for LLC is usually silica coated with a thin film of liquid. The latter is the stationary phase itself. The coating is performed by treatment of the silica by a solution of this liquid in a suitable solvent and subsequent displacement of the solvent by mobile phase. NP-LLC occurs when the stationary phase is polar contrary to RP-LLC where the stationary phase is nonpolar.

## Detailed Mechanisms

The mechanism in LLC is partition of the analyte between two immiscible liquids with different polarity. Analyte retention is governed by the different dissolution of the analyte components in both liquid phases.

In the case of NPLC, the stationary phase is polar (silica, alumina, or polar-bonded phase) and the mobile phase is nonpolar (hexane, heptane, etc.). Adsorption mechanism operates and involves adsorption of an analyte by its polar groups on the polar active sites of the stationary phase. Adsorption occurs by polar interactions and formation of hydrogen bonds. The nonpolar mobile phase cannot interact with the adsorbent-active sites and thus its adsorption practically does not occur. However, the mobile phase favors the analyte desorption interacting by dispersion forces with its nonpolar groups that are not involved in the adsorption. This is illustrated in **Figure 2** for analysis of an alcohol on silica. This case will be discussed again below. Thus, analyte molecules adsorb and desorb constantly, being

**Figure 2** Detailed adsorption mechanism of retention of an alcohol ROH in NPLC. A, adsorption by hydrogen bonds; D, desorption by dispersion forces.

connected with the stationary phase and mobile phase, respectively. For the time of analysis, the analyte, according to its structure, moves with the mobile phase and this determines its retention in the chromatographic system used. For instance, let us consider NPLC of two alcohols ROH with different length of the R group: hexyl ( $C_6H_{13}$ ) and octyl ( $C_8H_{17}$ ). Hexanol is more polar than octanol. Consequently the first alcohol will be adsorbed stronger (greater retention) than octanol, i.e., the retention order is  $C_6H_{13}OH > C_8H_{17}OH$ . This is an established fact. The adsorption mechanism accounts for the following retention order within organic compounds with the same R group:

- alkane (RH) < haloalkane (RHal)
- < alkene (RH as R contains one double bond)
- < ether ( $ROCH_3$ ) < ester ( $RCO_2CH_3$ )
- < ketone ( $RCOCH_3$ ) < aldehyde ( $RCHO$ )
- < carboxylic acid ( $RCO_2H$ )

Moreover, a higher homolog is less retained than a preceding homologue.

In the case of RPLC, the stationary phase is non-polar (nonpolar-bonded silica) and the mobile phase is polar. Polar mobile phase is, e.g., methanol/water. The mechanism in this case is considered as partition or adsorption. Partition in the sense of different solubility in both phases does not operate. In some cases water is the stationary phase enabling different partition of an analyte in water and the mobile phase. In RPLC, water is a mobile-phase component and thus it cannot be both stationary and mobile phase. Consequently, adsorption seems to govern retention in this case. **Figure 3** shows an illustration of the expected adsorption mechanism of an alcohol  $R^1OH$ . The alkyl groups R on the surface of the stationary phase, being its active sites, adsorb alcohol molecules. Adsorption between R and  $R^1$  takes place by dispersion forces of interaction. The polar mobile phase has negligible adsorption on the nonpolar stationary phase. However, it can lead to analyte desorption interacting with its polar (OH) group. Such a mechanism is supported by the fact that the retention of an analyte is greater on RP-18 than on RP-8. The longer  $C_{18}$  carbon chain is expected to lead to a stronger adsorption by dispersion forces. Moreover, separation of hexanol and octanol in this case will

**Figure 3** Detailed adsorption mechanism of retention of an alcohol  $R^1OH$  in RPLC. A, adsorption by dispersion forces; D, desorption by hydrogen bonds.

lead to greater retention of octanol owing to its longer carbon chain:  $C_8H_{17}OH > C_6H_{13}OH$ . This is indeed established in RPLC. Thus, the opposite retention order in this case relative to NPLC is reasonable on the basis of the adsorption mechanism described.

In the case of ion-exchange chromatography, the mechanism involves ion exchange with a competition between the analyte X ions and mobile-phase Y ions for interaction with R ions at the surface of the stationary phase. Electrostatic attractions require interaction of ions of opposite charges. Two cases are possible: anion-exchange chromatography where X and Y are anions and R is positively charged. The opposite is true for cation-exchange chromatography:

Let us consider a concrete example: separation of acetic acid and propionic acid on a cation exchanger with  $SO_3H$  groups on its surface and water containing NaOH ( $pH > 7$ ) as a mobile phase. Mobile phase passing through the column converts the strong acidic  $SO_3H$  group in its salt form and thus  $Y^+ = Na^+$ . Acetic acid is a stronger acid with a greater ionization than that of propionic acid and this determines the better retention of acetic acid. Thus, the retention expected in this case is: acetic acid  $>$  propionic acid.

In the case of size-exclusion chromatography, retention mechanism depends on geometrical factors only and does not include any interaction between the three components of the chromatographic system. This chromatographic method is useful for analysis of high molecular mass compounds. Let us consider a simpler case. Separation of hexanol and octanol will lead to a greater retention of hexanol:  $C_6H_{13}OH > C_8H_{17}OH$ . This is due to the smaller size of hexanol and its possibility to enter the inner pores of the stationary phase particles. On the other hand, octanol moves faster with the mobile phase outside the particles.

Retention in LC depends on retention mechanism and conditions used such as: stationary phase type, mobile-phase composition including its pH, flow rate, gradient applied if any, etc.

## Theory

There are many theories describing the LC system from different points of view. Analyte is characterized by its retention in such a system. Theoretical treatment of retention is closely related with the important problem for method development. Brief description of retention as a function of analyte structure or other factors is given.

### Retention versus Analyte Structure

The displacement model elaborated by Snyder in the 1960s to 1980s is well suited to explain retention in NPLC. On the basis of this model, chromatographic system is described quantitatively with various equations. According to the displacement model there is a competition between an analyte X and a mobile phase M for adsorption on the stationary-phase (adsorbent) active sites:

where subscriptions a and n denote adsorbed and nonadsorbed state, respectively.  $K$  is the equilibrium constant. The use of a mobile phase with a strong adsorption will leave X nonadsorbed (small retention) since equilibrium [4] is shifted to the left. An increase or decrease in retention is performed by the use of mobile phase with smaller or greater adsorption. This criterion is used in selection of suitable mobile phases for a specific separation. It allows retention to be adjusted to a favorable range ( $1 < k < 20$ ). To tune retention of the vast number of organic compounds, mobile phases, composed of two or more solvents, are usually used. For instance the retention of an alcohol is significant and its analysis cannot be done with hexane alone as a mobile phase. Mixtures of hexane and other polar solvents such as acetone are necessary. This increases the adsorption of the mobile phase and thus reduces retention of the alcohol. In such a case, acetone from the mobile phase competes with the alcohol for adsorption on the active sites.

Retention is a function of the parameters related with the adsorption properties of stationary phase, mobile phase, and analyte being characterized in the Snyder theory by various dimensionless parameters.

**Parameters characterizing the adsorption properties of stationary phase (adsorbent)** These parameters are selectivity  $\alpha'$  and a complex parameter  $\log (V_a W / V^o)$ .  $V_a$ ,  $V^o$ , and  $W$  are the volume of an adsorbed monolayer of mobile phase per gram adsorbent, volume of the pores surrounding the adsorbent particles (the so-called void volume), and mass of

the adsorbent in the chromatographic system, respectively. The complex parameter is denoted as  $R_{M(\text{shift})}$  since the retention of an analyte is changed or shifted when different adsorbents and the same mobile phase are used. Parameter  $\alpha'$  is related to the number of active sites per unit adsorbent area and parameter  $R_{M(\text{shift})}$  is related to the surface area of the adsorbent.

**Parameters characterizing the adsorption properties of mobile phase** Mobile-phase strength  $\varepsilon$  measures its dimensionless energy of adsorption ( $\Delta G^o / RT \ln 10$ ) per unit area. The greater the value of  $\varepsilon$ , the greater the adsorption of the mobile phase and this results, on the basis of eqn [4], in smaller retention. Parameters that tune the adsorption properties of mobile phase are localization  $m$  and polarity  $P'$  measuring the relative geometry under adsorption and solvating ability of the mobile phase. Localization is connected with the most favorable orientation for adsorption. It is characteristic for both mobile phase and analyte that adsorb in turn according to the displacement model. The strongest adsorbing group in the structure of a solvent or sample is localized and the remaining groups are delocalized. Localization is illustrated in Figure 4 (the carbonyl group only is localized). Mobile phases having a given value of  $\varepsilon$  and different values of  $m$  have different selectivity, i.e., different possibility to separate compounds. In general, a mobile phase having a higher value of  $P'$  dissolves the analyte better and thus decreases its retention  $k$ . The values of  $\varepsilon$ ,  $m$ , and  $P'$  of pure solvents used in LC are known. Some examples are shown in Table 1 where the elutropic series of solvents is given, i.e., the solvents are arranged according to an increase of their value of  $\varepsilon$ . The elutropic series begins with pentane and hexane having  $\varepsilon = 0$  and ends with methanol ( $\varepsilon = 0.70$ ). Table 1 shows also the relevant values of  $m$  and  $P'$ . Calculation of  $\varepsilon$  and  $m$  of mobile phases composed of two or more solvent requires a lot of calculations. Details are not included in this article. The values of  $P'$  are easily found on the basis of percent quantity,  $P_i$ , and individual polarity  $P'_i$  of any solvent  $i$  participating in the mobile-phase composition.

**Figure 4** Illustration of localization,  $m$ . The carbonyl group has a greater energy of adsorption and is localized while the double bond is delocalized.

**Table 1** Elutropic series of some pure solvents used as mobile phases in liquid chromatography and the relevant values of  $\epsilon$ ,  $m$ , and  $P'$ 

No.	Solvent	$\epsilon$	$m$	$P'$
1	Pentane	0.00	—	0.00
2	Hexane	0.00	—	0.10
3	Heptane	0.00	—	0.20
4	Tetrachloromethane	0.11	−0.35	1.60
5	Toluene	0.22	−0.43	2.40
6	Benzene	0.25	−0.42	2.70
7	Chloroform	0.26	0.10	4.10
8	Dichloromethane	0.30	0.10	3.10
9	Diethyl ether	0.43	0.66	2.80
10	Tetrahydrofuran	0.48	1.00	4.00
11	Ethyl acetate	0.48	0.60	4.40
12	Methyl- <i>tert.</i> butyl ether	0.48	—	2.70
13	Acetonitrile	0.52	1.50	5.80
14	Acetone	0.53	0.95	5.10
15	Isopropanol	0.60	—	3.90
16	Ethanol	0.65	1.05	4.30
17	Methanol	0.70	—	5.10

**Parameters characterizing the adsorption properties of the analyte** These parameters are energy of adsorption  $S_X$  and area under adsorption  $A_X$  of an analyte X. They are additive parameters and are calculated by summation of the relevant contributions of the individual structural fragments or functional groups  $i$  available in the analyte structure. A group  $i$  is characterized by its energy of adsorption  $Q_i^0$  and area under adsorption  $a_i$ :

$$S_X = \sum_i Q_i^0 \quad [5]$$

$$A_X = \sum_i a_i \quad [6]$$

There are literature data about  $Q_i^0$  and  $a_i$  of the usual groups  $i$  participating in the structure of organic compounds. The values differ if the group is connected with an alkyl or aryl group. Table 2 shows some examples. On the basis of these data,  $S_X$  and  $A_X$  of a specific compound become known. The greater the value of  $S_X$ , the stronger the analyte adsorption.

Parameters  $k$ ,  $\alpha'$ ,  $R_{M(\text{shift})}$ ,  $S_X$ ,  $A_X$ , and  $\epsilon$  are related by the Snyder theory in an equation having two forms:

$$R_M = \log k = R_{M(\text{shift})} + \alpha'(S_X - \epsilon A_X) \quad [7]$$

and

$$R_M = \log k = R_{M(\text{shift})} + \alpha' \left( \sum_i Q_i^0 - \epsilon \sum_i a_i \right) \quad [8]$$

Equation [7] is derived on the basis of eqn [4]. Its equilibrium constant  $K$  is expressed as a function of

(1) molar fractions of the four components of eqn [4], (2) free energy of adsorption by Gibbs equation, and (3) any one of the chromatographic parameters  $K_D$  and  $k$ . Equations [7] and [8] are used to determine one or two of their parameters when the other parameters are known.

In the Snyder theory, eqn [8] is the simplest equation that gives the relationship between retention and analyte structure. It is used in an approach for selection of suitable mobile phases for a given separation. The adsorbent, that will be used, is to have known values of  $\alpha'$  and  $R_{M(\text{shift})}$ . Otherwise, these values can be easily found. The relevant structural elements or functional groups (see Table 2) are used to express the structure of an analyte and find its values of  $S_X$  and  $A_X$  by eqns [5] and [6], respectively. The retention of an analyte on the selected adsorbent is calculated by eqn [8] when successive values, in the range of 0–0.70, are ascribed to  $\epsilon$ . An analysis of the retention as a function of  $\epsilon$  is performed for all compounds that will be separated. It allows predicting the optimum value of  $\epsilon$  for the concrete separation. Specific mobile phases having that value of  $\epsilon$  are found.

This approach is applicable if the analyte is a non-ionic organic compound and its structure is known. It is already successfully applied by means of a software (LSChrom) to normal-phase liquid chromatography (NRLC) of compounds with relatively simple or complex structure.

## Retention versus Other Factors

Retention indirectly reflects analyte structure. Consequently, it can be related to other parameters not connected directly to structure. There are various relationships in this respect. Attention will be focused on some relationships of this type where retention is a function of mobile-phase composition, keeping stationary phase and analyte the same. For instance, eqns [9] and [10] express the relationships between retention and mobile-phase polarity  $P'$  in the case of NPLC and RPLC, respectively:

$$\frac{k_2}{k_1} = 10^{(P'_1 - P'_2)/2} \quad [9]$$

$$\frac{k_2}{k_1} = 10^{(P'_2 - P'_1)/2} \quad [10]$$

when an analyte is analyzed with mobile phases 1 and 2 with different  $P'$  values. The subscripts to  $k$  and  $P'$  correspond to the mobile phases used. It is worth noting that mobile-phase strength in NPLC is better expressed by  $\varepsilon$ .

These and similar relationships are useful in selection of an optimum mobile phase necessary to separate complex mixtures of compounds. In general, the strategy used includes: (1) preliminary analysis with some concrete mobile phases on a given stationary phase, (2) application of a specific numeric method for analysis of the data collected using appropriate software, (3) selection of the optimum mobile-phase composition ensuring retention in the favorable range ( $1 < k < 20$ ) and maximum resolution  $R$  of all compound pairs, and (4) performance of an analysis with the optimum mobile phase selected. It is clear that this strategy requires preliminary experiments contrary to the strategy described when the analyte structure is directly taken into account. The strategy discussed is applicable both to any kind of LC since the precise mechanism of retention is indirectly taken into account by the mathematical modeling of the chromatographic system (point 2). It is an application of chemometrics in LC. The outlined strategy is used for separation of a complex mixture of compounds with the optimum mobile phase. The latter is selected on the basis of seven preliminary experiments with mobile phases with different composition. The mobile phases are composed of three to four solvents from different groups and properties. Mobile-phase properties are taken into account by localization,  $m$ . Numeric method used is overlap resolution map: the optimum mobile phase avoids overlap of the peaks of all pairs of compounds.

The strategy outlined has some modifications. It is developed by including other factors such as flow

rate, bed length, mobile-phase pH, design of the gradient change of mobile-phase composition, etc. The DRYLAB software is of importance in this respect. Such use of the multifactorial analysis is applicable to select suitable conditions in all liquid chromatographic methods: NPLC and RPLC, ion-exchange chromatography, and size-exclusion chromatography.

## Troubleshooting

The HPLC chromatograph is a complex instrument requiring maintenance of all its parts. Air bubbles in the mobile phase seen in the inlet tubings and leaking fittings prevent the proper operation of the chromatograph and give unreliable data. Mechanical particles in the analyte solution can damage both the syringe for its injection and column. Thus precautions in this respect are necessary. The quantity of the sample injected and the operating wavelength of the UV detector, if used, are to adjust properly. A high quality column is important. Taking these factors into account makes the analyses easier. Any specific problem that arises requires a specific response for its elimination. This is known as troubleshooting.

## Recommendations

A new separation by LC includes several steps. An important step is selection of suitable LC method and technique. The following recommendations are useful.

1. Try NPLC for separation of nonionic organic compounds which are dissolved well in mixtures of organic solvents. Apply it for separation of isomers and preparative separations. Adjust mobile phase pH if analytes are bases ( $\text{pH} > 7$ ) or acids ( $\text{pH} < 7$ ), thus avoiding chemisorption and tailing.
2. Try RPLC for separation of all kinds of nonionic organic compounds.
3. Try ion-pair LC for ionic or ionizable organic and inorganic compounds especially bases.
4. Try ion-exchange LC for separation of mixtures of inorganic ions, proteins, and related compounds.
5. Try size-exclusion LC for separation of high molecular mass samples (proteins, synthetic polymers, etc.).

Adjustment of pH is recommended in items 2, 3, and 4, if necessary.

If the first attempted LC method does not give good results, try another. Keep in mind the efficiency of the chromatographic system used. Adjust its selectivity with the aid of mobile-phase composition, number of theoretical plates, and flow rate (by means of Van Deemter equation).

Full method development is necessary in case of difficult separation with peak overlap and routine analyses.

The available software products in LC will assist one in dealing with chromatograms and selection of suitable experimental conditions.

Patience is required since any separation needs more or less time to settle the proper conditions. Going into depth of LC theory will assist one. However, this can be omitted if one has no time for it. Instead one should rely on the software products where relevant theoretical aspects are incorporated.

## Introduction

High-performance liquid chromatography (HPLC) has become one of the more important tools in the chemical analysis of mixtures, especially in the pharmaceutical industry. This would not have become possible without the workhorse of HPLC, the column. In the following, we will describe the characteristic properties of HPLC columns, starting with column physics, followed by column chemistry. In the column physics section, we discuss the choices in column length and column diameter, together with particle size, pore size, and particle porosity. In the discussion of column chemistry, we begin with a description of the base particles, followed by the different options available for surface chemistry. In the last section, we identify the chromatographic selectivity arising from this surface chemistry for packings used in reversed-phase chromatography. For a deeper discussion, the reader is referred to textbooks on column technology or chromatography.

## Column Physics

Most high-performance packings are based on silica or related hard particles, such as inorganic-organic hybrid packings. Therefore, the focus of the following discussion is the performance of incompressible packings.

The correct selection of column length and particle size is important for the separation power as well as the speed of analysis that is achievable with a given column. The compromise between speed and resolving power is shown in **Figures 1A** and **1B** for columns packed with 5  $\mu\text{m}$  and 3  $\mu\text{m}$  particles respectively. The achievable resolving power (= the square root of the column plate count) is plotted as a function of the analysis time. We implicitly assume an isocratic analysis to a retention factor of 10. Longer columns provide a higher resolving power, but cannot provide short analysis times due to the pressure limitations of the HPLC instrument. This is especially important for the smaller particles. A 25 cm column packed with 3  $\mu\text{m}$  particles can deliver much resolving power, but at the expense of a high pressure drop. The pressure limit constrains the flow-rate range over which the column can be used. For faster analyses, on the other hand, it is best to use shorter columns. For example, the performance of a

## Introduction

High-performance liquid chromatography (HPLC) has become one of the more important tools in the chemical analysis of mixtures, especially in the pharmaceutical industry. This would not have become possible without the workhorse of HPLC, the column. In the following, we will describe the characteristic properties of HPLC columns, starting with column physics, followed by column chemistry. In the column physics section, we discuss the choices in column length and column diameter, together with particle size, pore size, and particle porosity. In the discussion of column chemistry, we begin with a description of the base particles, followed by the different options available for surface chemistry. In the last section, we identify the chromatographic selectivity arising from this surface chemistry for packings used in reversed-phase chromatography. For a deeper discussion, the reader is referred to textbooks on column technology or chromatography.

## Column Physics

Most high-performance packings are based on silica or related hard particles, such as inorganic-organic hybrid packings. Therefore, the focus of the following discussion is the performance of incompressible packings.

The correct selection of column length and particle size is important for the separation power as well as the speed of analysis that is achievable with a given column. The compromise between speed and resolving power is shown in **Figures 1A** and **1B** for columns packed with 5  $\mu\text{m}$  and 3  $\mu\text{m}$  particles respectively. The achievable resolving power (= the square root of the column plate count) is plotted as a function of the analysis time. We implicitly assume an isocratic analysis to a retention factor of 10. Longer columns provide a higher resolving power, but cannot provide short analysis times due to the pressure limitations of the HPLC instrument. This is especially important for the smaller particles. A 25 cm column packed with 3  $\mu\text{m}$  particles can deliver much resolving power, but at the expense of a high pressure drop. The pressure limit constrains the flow-rate range over which the column can be used. For faster analyses, on the other hand, it is best to use shorter columns. For example, the performance of a

**Figure 1** Resolving power ( $= \sqrt{N}$ ) of various columns as a function of analysis time. It is assumed that the analysis is completed at  $k=10$ . Performance of (A) 5  $\mu\text{m}$  columns and (B) 3  $\mu\text{m}$  columns. The column lengths are 25, 15, 10, and 5 cm.

5 cm 5  $\mu\text{m}$  column matches that of a 10 cm 5  $\mu\text{m}$  column for a 2 min analysis, but at a lower pressure drop. The analysis time can be reduced to less than half a minute if only a performance of 600 plates is needed.

An interesting aspect of column design is the fact that the same maximum plate count is achievable when the column length and the particle size are changed in the same proportion. A 10 cm 10  $\mu\text{m}$  column, a 5 cm 5  $\mu\text{m}$  column, and a 3 cm 3  $\mu\text{m}$  column all achieve the same maximum resolving power,  $\sim 4500$  plates. However, the analysis time at which this performance can be reached decreases with the square of the particle size. The same resolution that can be achieved in  $\sim 75$  min with the 10  $\mu\text{m}$  column can be reached in under 7 min with the 3  $\mu\text{m}$  column. In addition, for a particular analysis time, the backpressures of a 10 cm 10  $\mu\text{m}$  column, a 5 cm 5  $\mu\text{m}$  column, and a 3 cm 3  $\mu\text{m}$  column are identical. This is the primary advantage of small particles.

In principle, the column diameter does not have an influence on the relationship between plate count, pressure, and analysis time. Only in very narrow columns, where the column diameter is less than 10

times the particle diameter, a loose bed with a higher permeability (= lower backpressure) is formed. If the available sample mass is limited, higher sensitivities are achieved if the available sample mass is injected onto a smaller-diameter column. However, if the sample volume is not constrained, better sensitivity can be reached with a standard column with standard detectors. This is because the signal-to-noise ratio decreases with the detector volume for concentration-sensitive detectors.

To maximize the retention, fully porous particles are used in most HPLC applications. The pore size determines the surface area that is available. Packings with a smaller pore size have a larger specific surface area, but this restricts the access for larger molecules. Therefore, packings designed for the analysis of small molecules have typically a pore size of 10 nm, while packings used in the separation of proteins have a pore size of 30 nm or even 100 nm. The increase in pore size leads to a reduction in surface area. For the separation of very large molecules, nonporous particles with a particle diameter around 1–2  $\mu\text{m}$  are advantageous.

The specific pore volume determines the strength of the particle. Packings with a pore volume  $\sim 1.5 \text{ ml g}^{-1}$  are very fragile, and those with values  $\sim 0.5 \text{ ml g}^{-1}$  are indestructible under normal HPLC conditions. Many HPLC packings have a specific pore volume around or just under  $1 \text{ ml g}^{-1}$ . The retentivity of a packing is best described by the ratio of surface area to pore volume. A packing with a specific surface area of  $350 \text{ m}^2 \text{ g}^{-1}$  and a specific pore volume of  $0.9 \text{ ml g}^{-1}$  is about as retentive as a packing with a surface area of  $190 \text{ m}^2 \text{ g}^{-1}$  and a pore volume of  $0.5 \text{ ml g}^{-1}$ . There is a close link between the specific surface area  $A_{\text{sp}}$ , the specific pore volume  $V_{\text{sp}}$ , and the pore size  $d_{\text{po}}$ :

$$\frac{A_{\text{sp}}}{V_{\text{sp}}} \approx \frac{c}{d_{\text{po}}}$$

The value of  $c$  is  $\sim 3.75$ . Thus, the pore size is the determining factor for the retentivity of a packing. The catalogs of column manufacturers supply at least two of these values.

In recent years, monolithic columns have been developed. While classical columns are packed with particles, monolithic columns are continuous structures that look like corrals. The skeleton can be porous, like particles, and contains the surface area responsible for retention. The space between the skeleton provides the flow passages. The key advantage of monolithic columns lies in the fact that the interstitial space can be manipulated independently of the domain size that is responsible for retention. Therefore, the compromise between column

performance and backpressure is more favorable for well-designed monolithic columns. However, the mere fact that a column device is monolithic does not yet mean that a favorable performance has been achieved. The best measure for the comparison of a monolithic device to a packed bed is created if a particle size equivalent is generated from the backpressure of the device. With this measure, a well-designed monolith outperforms a packed bed by a factor of  $\sim 2$ , meaning that current monoliths achieve the same performance as 5  $\mu\text{m}$  columns at a backpressure typical of 10  $\mu\text{m}$  columns.

## Column Chemistry

### The Base Packing

HPLC packings may be based on several different raw materials. Silica, zirconia, titania, and alumina are the inorganic carriers that are used. Silica hybrids are also predominantly inorganic at the time of this writing. Organic polymeric packings, e.g., packings based on styrene–divinylbenzene or methacrylate, are used mainly for size-exclusion chromatography or for the analysis of biomolecules such as proteins. Porous graphitic carbon is used for some specific applications in reversed-phase chromatography. In contrast to inorganic packings, polymeric packings deform under pressure. Therefore, only lower pressures can be applied. The pressure limit depends on the details of the design of the packing.

**Figure 2** Silanol groups on the surface of silica: (A) geminal; (B) vicinal; and (C) lone silanols. Silicon atoms are connected to each other via siloxane bridges.

Silica can be used in the acidic pH range up to pH 8. Zirconia and styrene/divinylbenzene-based packings can be exposed to any pH without damage. Methacrylate packings are stable from pH 2 to pH 12. The pH stability of hybrid organic–inorganic packings depends on the design of the packing, and extends from the acidic pH to pH 12. The pH stability of alumina extends to pH 13.

Silica and silica hybrids are the bases for the most popular HPLC packings. The surface of silica is covered with silanol groups. These are subdivided into geminal, vicinal or bridged, and lone silanols, as shown in **Figures 2A–2C** respectively.

The concentration of surface silanols depends on the treatment of the silica. It is usually assumed that  $\sim 8 \mu\text{mol m}^{-2}$  cover the surface of a fully hydroxylated silica.

In silica hybrid packings, some of the siloxane bridges are substituted by methyl groups or by ethylene bridges, as shown in **Figure 3**.

### The Stationary Phase

While silica or silica hybrid packings are active sorbents on their own, their surfaces are commonly derivatized with a silanization reagent. The chromatographic properties of these bonded phases are determined by the reagent as well as the derivatization technique. A reaction with monofunctional, difunctional, and trifunctional silanes is possible (**Figure 4**). The reagent, which can be either an alkoxy silane or a chloro silane, is shown on the left, and a cartoon of the resulting surface derivatization is found on the right. The surface of the silica itself is indicated with a horizontal bar. With trifunctional reagents (**Figure 4A**), additional silanols are produced during the bonding step, because the reagent reacts with the surface only via two surface silanols. Difunctional reagents (**Figure 4B**) react with the surface silanols predominantly in a two-bite reaction, but additional silanols are created for the fraction of the reagent that reacts only with one bite. With a monofunctional silane (**Figure 4C**), only  $\sim 4 \mu\text{mol m}^{-2}$  or less

**Figure 3** Structure of an ethyl-bridged silica hybrid packing. The ethyl groups reduce the number of surface silanols and provide chemically stable bridges between the different layers of the backbone of the packing.

With difunctional reagents (**Figure 4B**), both ligands  $R_1$  and  $R_2$  can be the same. However, for most bonded phases based on a difunctional silane, the second ligand is commonly a methyl group. In **Figure 4C**, the methyl group is shown as the common side chain for monofunctional bonded phases. Alternatively, isopropyl or isobutyl groups provide an increase in the hydrolytic stability of the packing under acidic conditions. At the same time, the bulky side groups limit the surface coverage that can be achieved, which results in a larger silanol activity

(A) Chemical structure of a siloxane network. The network consists of a horizontal chain of silicon (Si) atoms connected by oxygen (O) atoms. Each silicon atom in the chain is also bonded to two oxygen atoms, which are further bonded to a second layer of silicon atoms. The second layer of silicon atoms is also connected by oxygen atoms. The first layer of silicon atoms has pendant groups: the first silicon atom has two 'X' substituents, and the other three silicon atoms have one 'R' group and one 'H' atom. The second layer of silicon atoms has pendant groups: the first silicon atom has one 'R' group and one 'H' atom, and the other three silicon atoms have one 'R' group and one 'H' atom.

A range of bonded phases are commercially available. They can be classified into bonded phases for reversed-phase chromatography and bonded phases with specific ligands that can be used for other types of chromatography. A selection of ligands used in reversed-phase chromatography is shown in **Figures 5 and 6**. As above, the nature of  $X_1$  and  $X_2$  varies, depending on whether monofunctional, difunctional, or trifunctional ligands are used. The classical

Chemical structures of various siloxane compounds:

- Linear siloxane with a long alkyl chain (10 carbons).
- Linear siloxane with a medium alkyl chain (6 carbons).
- Linear siloxane with a short alkyl chain (4 carbons).
- Trimethylsiloxane.
- Phenylsiloxane with a 3-phenylpropyl chain.

ligands shown in Figure 5 range from the popular  $C_{18}$  phases to shorter chains such as  $C_8$ ,  $C_4$ , or  $C_1$  phases. The latter two are most frequently applied for the separation of proteins. Commercial phenyl phases have different alkyl chains between the phenyl groups and the silicon atom. Only one possible structure is shown. Due to a unique steric selectivity, phases with a  $C_{30}$  ligand (not shown) are used for the separation of carotenoids.

The reversed-phase ligands in Figure 6 contain an embedded polar group, which reduces substantially the interaction of analytes with residual silanols on the surface and thus improves the peak shapes. Some of the packings with an embedded polar group are synthesized in two steps. The first step is a surface derivatization with a propylaminosilane. In the second step, the reversed-phase ligand is attached to the amino group via an amidation reaction. Due to steric hindrance, surface reactions are never complete. Consequently, residual  $-NH_2$  groups remain on the surface of those packings that are synthesized in two

steps. This can be avoided if the ligand is assembled first and reacted onto the silica surface in a single step.

Occasionally, one would like to separate rather polar compounds with a reversed-phase technique. This requires packings that can function well in a 100% aqueous mobile phase. This is not the case for highly covered and fully endcapped  $C_{18}$  phases. The unfavorable wetting angle of these packings toward water drives the mobile phase out of the pores and causes loss of retention. This can be manipulated by a judicious choice of the coating level (Atlantis d $C_{18}$ ), the incorporation of polar groups into the ligand (e.g., SymmetryShield RP $_{18}$ ), polar endcapping, or no endcapping (e.g., Resolve  $C_{18}$ ).

Ligands with polar functional groups and fluorinated phases are shown in Figure 7. Pentafluorophenyl packings and perfluorinated alkyl packings are utilized in reversed-phase chromatography. Cyano and nitrophenyl packings are useful both in normal-phase and in reversed-phase HPLC. The primary use

**Figure 7** Packings with other functional groups: (A) pentafluorophenyl, (B) cyanopropyl, (C) nitrophenyl, (D) aminopropyl, (E) zwitterionic phase, and (F) diol packing.

of aminopropyl packings is in the analysis of carbohydrates in hydrophilic interaction chromatography (HILIC). HILIC is an extension of normal-phase chromatography to mobile phases containing 10–50% water. This technique requires very polar stationary phases. The zwitterionic stationary phase shown in **Figure 7E** is also predominantly employed in HILIC separations. Diol packings can be used for both aqueous size-exclusion chromatography as well as for normal-phase separations.

The hydrolytic stability of silica-based packings depends on the nature of the ligand and the pH of the mobile phase. At acidic pH, the ligand is cleaved off the surface. Under alkaline conditions, the stability depends primarily on the nature of the matrix. Above pH 8, silica dissolves. Methyl hybrids or ethyl-bridged hybrids can be used up to pH 12. At acidic pH, packings based on trifunctional silanes have a better stability than packings based on monofunctional silanes. The best lifetime under acidic conditions is obtained with packings with a bulky side group. A longer chain length, i.e., a C<sub>18</sub> packing, is more stable than a shorter chain length, e.g., a CN packing. Most manufacturers recommend a pH range from 2 to 8 for standard silica-based packings.

## Selectivity of Reversed-Phase Packing

Several hundred reversed-phase materials are commercially available. The majority of them are C<sub>18</sub>-type packings. However, they are by no means interchangeable with each other. The reasons for this are differences in the coating levels, the purity of the base silica, the efficiency of the endcapping procedures, the ligands used, and the nature of the

endcapping reagents. This results in a broad range of retention and selectivity properties, as well as differences in the hydrolytic stability and reproducibility of these packings.

For the user of HPLC columns, the most important features are the chromatographic selectivities of the different packings. In the following, we will categorize reversed-phase packings using measures of their hydrophobicity, silanophilic interaction at pH 7, hydrogen-bond formation, and their steric selectivity.

The hydrophobic retentivity of a packing can simply be measured using the retention factor of a neutral hydrocarbon such as acenaphthene. The silanophilic interaction can be derived from the relative retention between amitriptyline, a hydrophobic base, and acenaphthene. From both parameters, a map of two of the fundamental properties of an HPLC packing can be constructed. A chart of these two primary properties of reversed-phase packings is shown in **Figure 8** for over 100 different commercially available columns. The x-axis represents the hydrophobicity of the packings, and the y-axis is a measure of the silanophilic interaction at pH 7. This parameter may also be viewed as a measure of the ion-exchange properties due to residual silanols. The right-hand side of the graphs contains packings with a higher hydrophobicity, and the left-hand side contains packings with a decreased hydrophobicity. In **Figure 8A**, the left-hand side is occupied by cyano and phenyl packings. **Figure 8B** is an expansion of **Figure 8A** and contains predominantly C<sub>8</sub> packings and C<sub>18</sub> packings with a low surface coverage on the left side, and fully coated C<sub>18</sub> packings on the right. The final expansion, **Figure 8C**, comprises, for the most part, high-purity C<sub>18</sub> packings.

The vertical axis is a measure of the deactivation of surface silanols. Packings with a high silanol

**Figure 9** Plot of polar selectivity versus hydrophobicity. Designations as in **Figure 8**.

activity are at the top, and those with a low activity are shown at the bottom. The inserted horizontal dotted line in **Figures 8A** and **8B** separates packings with embedded polar groups below the line from packings without this feature above the line. This demonstrates clearly the reduction of silanol activity with this type of bonded phase.

Both properties shown in **Figure 8** represent the most important attributes of a packing, but not the only ones. Packings exhibit other selectivity features as well. For example, the hydrogen-bond donor and acceptor properties can be measured using the relative retention between butylparaben and dipropylphthalate. These properties affect the selectivity of a packing for polar functional groups in a manner that is independent of the activity of residual silanols. A similar map as in **Figure 8** has been constructed for this polar selectivity in **Figure 9**. Generally, packings with embedded amide, carbamate, and urea groups excel at this feature, while classical  $C_{18}$  packings, shown at the bottom, lack this property. Packings below a polar selectivity value of  $\sim -0.4$  are classical bonded phases. In addition to these hydrogen-bond selectivity features, these packings are excellent for the separation of basic compounds, because they exhibit much less tailing than classical bonded phases.

Another important feature of a packing is its steric selectivity. It reflects the ability of a packing to discriminate between compounds that differ only in shape. The best-documented examples are polycyclic aromatic hydrocarbons, but the same feature is also

relevant for the separation of carotenoids and steroids, for example. For polynuclear aromatic hydrocarbons, it has been demonstrated that the shape selectivity correlates clearly with the bonding density of a packing. Thus, one can use the surface coverage, measured in  $\mu\text{mol m}^{-2}$ , as a measure of the steric selectivity of a packing. This property is commonly reported by the manufacturers of packings.

In summary, four parameters can be used to differentiate commercial silica-based HPLC packings: hydrophobicity as measured by the retention factor of a neutral hydrophobic compound; silanol activity as measured by the retention characteristic of a basic compound at neutral pH; hydrogen-bond acceptor/donor properties as measured by the relative retention of a hydrogen-bond donor and a suitable polar reference compound; and the steric selectivity measurable by the surface coverage of a packing. Packings that are close to each other in every one of these parameters are likely to give similar separations. On the other hand,  $C_{18}$  packings that are far away from each other have different retention properties. It is therefore important to specify the specific brand of a packing in publications or other documents.

## Introduction

Liquid chromatography (LC) is the term used to describe the separation of a solution following differential migration in a liquid flowing through a column packed with solid particles. Miniaturized liquid separation techniques began in the late 1960s. In 1967, Horváth *et al.* developed stainless steel columns ranging from 0.5 to 1.0 mm internal diameter (i.d.) packed with pellicular particles for the separation of nucleotides. In the mid-1970s, Ishii *et al.* prepared 0.5 mm i.d.  $\times$  1.5 m long columns using pellicular particles and introduced slurry-packed Teflon microcolumns. In the same decade, Scott *et al.* prepared 10 mm i.d.  $\times$  10 m long columns for the separation of alkylbenzenes. In the late 1970s and the early 1980s, improvements were made to the technique and in this way the criteria were set for the next three decades of research.

In conventional high-performance liquid chromatography (HPLC), columns are usually of 10–25 cm length and 2–4 mm i.d. Recently, capillary HPLC columns have become available in the market. The terminology, abbreviations, and definitions have not yet been standardized. In the literature, we can find microbore, micro-LC, semimicro-LC,

capillary-LC, and nano-LC. In general, microbore or narrow-bore columns are considered as those with an internal diameter of less than 2 mm. From 1 mm down, micro-LC is more appropriate. Capillary columns are described as those of less than 0.5 mm i.d. and nano-LC columns usually have an internal diameter of less than 0.1 mm.

The advantages of using microflows instead of normal flows are significant. An important advantage is the use of less mobile phase as illustrated in **Table 1**. This addresses both the cost of purchase and the cost of disposal of these solvents. It also diminishes the environmental impact of the toxic solvents. Arguably, the most important advantage of using microflow through capillary columns is the higher sensitivity that can be achieved. When scaling down the internal diameter of a column, the analysis becomes more sensitive. The increased mass sensitivity is attributed to the reduction in column internal diameter, which results in reduced dilution of the chromatographic band during analysis. This is very important when determining compounds present at low concentrations in limited sample volumes. Further, another important direct consequence of the

small flow rates delivered is the excellent conditions for coupling micro-HPLC to a mass spectrometer.

## The Rate Theory of Chromatography and Key Parameters

The rate theory of chromatography, also known as the van Deemter model, examines the factors affecting band broadening, which is the amount of dispersion of a sample as it migrates through a column.

The efficiency of the column can be approximated by the following expression known as the classical Knox equation:

$$H = Au^{1/3} + \frac{B}{u} + Cu \quad [1]$$

The equation tries to account for all the kinetic processes that occur when a separation is undertaken.  $A$ ,  $B$ , and  $C$  are coefficients that relate to the three different processes:  $A$  being the Eddy diffusion,  $B/u$  the longitudinal axial diffusion,  $Cu$  the mass transfer term, and  $u$  the mean linear velocity.

Van Deemter *et al.*, Giddings, Huber, and Horváth *et al.* have used alternative models to account for the relationship between the solute concentration in the stationary phase, its mobile phase concentration, and the various parameters characterizing the chromatographic system used. In general, when all the contributions of the parameters are accounted for, the separation will be performed at the flow depicted by the smallest  $H$  value, i.e., the greatest efficiency.

Efficiency is a measure of how well the chromatographic column is performing. Another term that accounts for efficiency is the value  $N$ , which is called the number of theoretical plates. The term 'plates' originates from the theory of distillation columns, where equilibrium between two phases occurs in each plate. For LC, a column can be thought of as a series of 'plates' where equilibration of the analyte occurs between two phases. The greater the number of theoretical plates the more efficient the separation.

A useful way of describing efficiency is by taking into account the length of the column  $L$ , in this way calculating the height equivalent to a theoretical plate  $H$  or HETP:

$$H = \frac{L}{N} \quad [2]$$

Hence, an efficient separation will have a small  $H$  value. When columns of various lengths are compared, it is more useful to use plates per meter  $N'$  as a measure of column efficiency:

$$N' = \frac{N}{l} \quad [3]$$

where  $l$  is the length of the column in meters.

$N$  is widely used to compare columns, but this can only be done when the particle size and test analytes are the same. The reduced plate height  $h$  can also be calculated, which takes into account the diameter of the particles  $d_p$ :

$$h = \frac{H}{d_p} \quad [4]$$

Next, we will consider the important factors when using these smaller diameters.

The down-scale factor was studied by Ryan in 1996 and it applies to all components and parameters of the system, such as flow rates, injection, detection volumes, and connecting capillaries. This factor is very important for the successful transfer of a conventional method to a microscale equivalent. The equation below shows that this factor is equal to the partition of the squares of both diameters:

$$f = \frac{d_{\text{conv}}^2}{d_{\text{micro}}^2} \quad [5]$$

where  $d_{\text{conv}}$  and  $d_{\text{micro}}$  are the diameters of the conventional and microscale columns.

### Flow Rates

When the column internal diameter is reduced, the mobile phase flow rate should also be reduced to maintain the same efficiency.

The column vacant volume can be expressed as

$$V_0 = \frac{1}{4}\pi d_c^2 \epsilon L \quad [6]$$

and the volumetric flow rate can be defined as

$$u = \frac{4F}{\pi d_c^2 \epsilon} \quad [7]$$

In order to maintain the same linear velocity for columns of different internal diameters, the volumetric flow rate should be decreased in proportion to the square of the ratio of the column internal diameters.

The linear velocity can also be expressed, based upon other column conditions, as

$$u = \frac{\Delta P d_p^2}{\Phi \eta L} \quad [8]$$

where  $\Delta P$  is the pressure drop across the column,  $d_p$  is the particle diameter,  $\Phi$  is the flow resistance parameter, and  $\eta$  is the viscosity of the mobile phase. Rearranging this equation gives:

$$\Delta P = \frac{\Phi \eta L u}{d_p^2} \quad [9]$$

This demonstrates that the column backpressure is independent of the column internal diameter. Therefore, microcolumns and analytical columns of the same length, packed with the same particles, and operated at the same linear velocity using the same mobile phase will generate similar backpressures. However, microcolumns are more susceptible to clogging; therefore, care must be taken by filtering solutions and samples. The use of low dead-volume inline-filters is also recommended.

### Injection and Detection Volumes

As the column diameter decreases, the loading capacity of the column also decreases, thus the maximum sample injection volume has to be reduced accordingly. The following equation describes the maximum injection volume that can be injected into a column:

$$V_{\max} = \frac{\theta K \pi \epsilon d_c^2 L (k + 1)}{\sqrt{N}} \quad [10]$$

where  $\theta$  is the fractional loss of the column plate number caused by the injection,  $K$  is a constant defining the injection profile,  $L$  is the length of the column,  $k$  is the retention factor, and  $N$  is the theoretical plate number.

The following equation relates the maximum sample mass to the maximum sample concentration that can be eluted from the column:

$$M_{\max} = \frac{C_m \pi \epsilon d_c^2 L k}{2\sqrt{N}} \quad [11]$$

In practice, as stated by Chervet, for a 75  $\mu\text{m}$  i.d.  $\times$  15 cm packed column, the maximum injected sample mass (loading capacity) for an unretained compound ( $k = 0$ ) should not exceed 50 ng.

With regards to the optimization of the detection volume, the scale-down factor can also be applied to eqn [2], and a good compromise between sensitivity, noise, and peak dispersion would consist in using detection volumes similar to injection volumes.

### Sensitivity Gain

What is the maximum sensitivity gain possible in liquid chromatography by decreasing the internal diameter of columns?

In 1995, Ryan proposed a model to adapt normal-flow chromatography to microflow chromatography. The theory states that when going from a column of diameter  $X$  to a smaller diameter  $Y$ , the gain in sensitivity would be equivalent to the partition of the squares of the internal diameters [ $X^2/Y^2$ ].

Thus, in practical terms, when adapting a method from a 2.1 mm i.d. column to a 0.5 mm i.d. column,

**Figure 1** The response on four columns of different diameters after injecting the same amount of sample; the sensitivity increases greatly with the smaller diameters.

there would be a sensitivity gain of  $2.1^2/0.5^2 = 17$ , i.e., 17 times more response would be observed. From a 2.1 mm column to a 0.3 mm column the sensitivity increase could be as big as 49 times. **Figure 1** illustrates the sensitivity gain going from a 1.0 mm i.d. column to a 0.3 mm i.d. column, after injecting the same amount of sample.

### Instrumentation

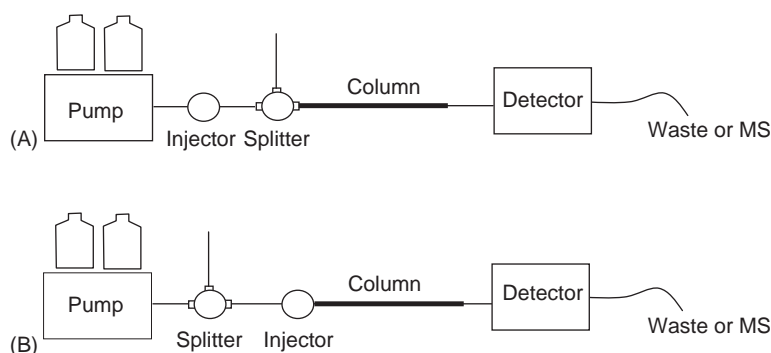

Today, micro-LC is a valuable analytical tool for sample-constrained applications such as proteomics and bioanalysis. The microliter flow rates are ideally suited for direct, splitless coupling with electrospray ionization mass spectrometry (ESI-MS). Many benefits can be demonstrated from well-established HPLC theory, which allows for direct method transfer to micro-LC.

Micro-HPLC has some key differences to conventional LC. Microbore columns require a very low flow rate, which needs to be delivered in a continuous flow. In generating sufficient flow through the columns, much higher backpressures are experienced, compared to standard HPLC. Also, the amount of analyte injected onto the column must be much lower, and all internal dead volumes must be minimized and reduced, otherwise band broadening effects will cause a significant problem.

Conventional HPLC instruments cannot meet these specific requirements, and therefore are simply not suitable for micro-LC. It is possible to downscale standard HPLC equipment by employing flow splitters, capillary flow cells, microconnectors, and fittings; however, these instruments can be unreliable.

The problems can be grouped into three categories:

- detector signal-to-noise,
- gradient formation, and
- flow splitting.

**Figure 2** Flow splitting device: (A) shows the injector before the splitter, which means that both the flow and the sample are split before going on to the column; (B) shows the injector after the splitter, so just the flow is being split, and a full sample injection is going on to the column.

The immediate result of attempts to scale down separations is a lack of detector sensitivity. Analytical detector flow cells introduce excessive band spreading and low peak response, drastically reducing peak capacity and making peak integration all but impossible. By simply using online detection methods, for example, passing the light across the capillary at the end of the column minimizes band spreading, but the short pathlengths can yield very low absorbance.

The other problem arises from the formation of accurate gradients under such low flow conditions. For gradients to be formed, one solvent must be accurately metered at only fractions of the total flow. One solution to this problem, ensuring microliter per minute flow rates, is to employ a flow splitter. Here, the flow is split into two separate paths depending on the backpressure of the restrictor used, allowing flow to the column and to waste. While the ratio of these two pressures remains constant, a consistent flow rate can be achieved; however, this ratio may change over time, due to the backpressure altering, resulting in the flow to the column changing. Another problem arising from splitting the flow as opposed to a system designed specifically to deliver microflows is the greater costs due to the high solvent consumption. **Figure 2** presents the two different configurations for flow splitting in micro-LC.

Micro-HPLC instruments are now commercially available and are designed to meet the exact requirements needed for microflows and offer the highest performance with ease of use. There are several micro/capillary LC instruments available in the market, and these include the Agilent 1100 Capillary LC™ system, LC packings Ultimate™ System, and Waters CapLC® System.

The Agilent 1100 Capillary LC works by splitting the relatively high flow rates to the column. The instrument utilizes a novel flow-monitoring device, called an electronic flow control, which monitors the

flow rate and adjusts it accordingly. The device works by measuring the actual flow rate, rather than using calculations.

This instrument is capable of providing flow rates as low as  $1 \mu\text{L min}^{-1}$ , running accurate gradients, and has a diode-array detector with a 500 nL flow cell.

#### Waters CapLC® System

The solvent delivery system in this instrument uses a syringe-style, positive-displacement, continuous delivery design. Each syringe is motor driven and software controlled so that crossover-related flow phenomena are eliminated. Gradients can also be performed, and are mixed under high pressure to minimize the gradient delay.

There is a dual wavelength detector, with patented low-volume flow cells (250 and 40 nL), which combines a long pathlength and high light throughput (CapLC cell). This focuses and guides light from a deuterium lamp source along the length of the flow cell.

Isocratic flow rates can be as low as  $250 \text{ nL min}^{-1}$ , while gradient flow rates can be generated from  $1 \mu\text{L min}^{-1}$ , while injection volumes can be as low as 20 nL.

#### Ultimate™ Fully Integrated Capillary HPLC System from LC Packings/Dionex

This instrument uses a helium sparging device with four separately controlled solvent lines, ensuring optimal solvent degassing and improving check valve reliability at low flow rates, diminishing baseline disturbances at low ultraviolet (UV) wavelengths.

The pumping system uses a high-precision reciprocating pump with proprietary microflow processing based on flow splitting. There are various calibrators that can be inserted to alter the extent of the flow splitting. This can generate flow rates from  $200 \mu\text{L min}^{-1}$  to  $50 \text{ nL min}^{-1}$ . The system uses a

microautosampler system to perform automated sample injection, but can also use a six-port low-dispersion injection valve for manual sample injection (1  $\mu\text{L}$  minimum).

The instrument has a specially designed scanning UV-visible absorbance detector, which can simultaneously monitor up to four different wavelengths. There are various interchangeable flow cells with volumes from 180 to 3 nL. They are used in conjunction with capillaries of 150 and 20  $\mu\text{m}$  i.d., respectively.

### Micropumps

Pumps are now available that can deliver micro- and nanoflows down to 100 nL min<sup>-1</sup>, without the need for flow splitters. These are generally reciprocating or syringe pumps.

One such pump is the MicroTech Ultra-Plus, which can deliver ultralow flows using a micro-reciprocating piston, which is precise and digitally controlled. This can deliver flow rates to a minimum increment of 0.1  $\mu\text{L}$  min<sup>-1</sup>, and gradient flow rates as low as 0.01  $\mu\text{L}$  min<sup>-1</sup> with a split, and 5  $\mu\text{L}$  min<sup>-1</sup> without a split.

Another pump, the Evolution 200, can also deliver low flow rates with high precision, with isocratic flows down to 0.1  $\mu\text{L}$  min<sup>-1</sup>, and gradient flows from 1  $\mu\text{L}$  min<sup>-1</sup>. This system uses binary high-pressure gradient formation with two linear drive piston pumps.

With the use of very low diameter columns, dead volume becomes a key problem, so manufacturers have gone to great lengths to try and minimize these effects. There are various column formats that have been employed for micro-LC, including fused silica capillary columns, glass-lined stainless steel, and glass-lined peek such as peeksil.

Columns for capillary LC are often prepared in fused-silica capillaries. These capillaries have a polyimide outer coating to increase the robustness of the column. Generally, the columns are packed with conventional HPLC chromatographic phases, with particle sizes of 3 and 5  $\mu\text{m}$  diameter. Frits have to be manufactured in order to retain the packing material, and can be made from sintering silica or directly sintering the packing material.

The column can be packed by various methods, but the most common method is to use a slurry of the stationary phase. Once the initial end frit has been manufactured, the capillary can then be attached to a packing reservoir, which contains a slurry of the stationary phase. The packing reservoir in turn is attached to a high-pressure packing pump that delivers the packing solvent. The packing material is

generally ultrasonicated during packing, to ensure a well-packed chromatographic bed, and then the second retaining frit is sintered directly from the packing material.

More recently, columns have been developed where the stationary phase is formed of a porous polymer network inside the capillary. These are called monolithic phases, and have emerged as an alternative to traditional packed bed columns for use in micro-HPLC. They hold many advantages over traditional packed bed columns, being easy to manufacture since the monolith is formed *in situ*, often via a one-step reaction process, and its properties such as porosity, surface area, and functionality can be tailored. Another major advantage is that they eliminate the need for retaining frits. These columns can be manufactured from a variety of materials, but the most common include sol-gel, methacrylate-based, acrylamide-based, and styrene-based polymeric structures.

There are a few commercially available monolithic columns on the market today, one of the first being the Chromolith<sup>TM</sup> from Merck, which uses a silica-based polymeric network for the high-speed separation of compounds of low to medium molecular weight at high flow rates with only low backpressures. More recently, LC Packings (a Dionex company) have released the Monolith<sup>TM</sup>, which is a polystyrene-divinylbenzene based monolith for the fast separation of proteins and peptides by micro LC.

## Applications of Micro-HPLC

Micro-HPLC has been used for the analysis of a wide variety of analytes, ranging from polyaromatic hydrocarbons (PAHs) and agrochemicals, to biomolecules. In these applications, the microcolumn (i.d. less than 1 mm) consisted of either a traditional packed bed or a monolith, i.e., a polymer network.

### Proteomics

Chen *et al.* reported the enantioseparation of dansyl amino acids on 100  $\mu\text{m}$  i.d. ligand exchange-chiral monolithic microcolumns. Using continuous beds modified with chiral selectors such as L-phenylalaninamide, L-alaninamide, L-prolinamide, he achieved efficiencies of  $\sim 1000$  plates per meter.

Czerwenka *et al.* successfully performed the enantiomeric separations of a series of alanine peptides derivatized with different N-protection groups on packed beds containing a chiral stationary phase modified with the chiral selector *tert*-butyl-carbamoylquinine.

Huber's research group reported the high-resolution separation of peptides and proteins on poly(styrene-divinylbenzene) (PS/DVB) monoliths coupled with ESI-MS detection. More particularly, they were capable of separating and detecting very small

**Figure 3** High-resolution capillary RP-HPLC separation of tryptic peptides of human transferrin in a monolithic column. Column, monolithic PS/DVB,  $60 \times 0.20$  mm i.d.; mobile phase: (A) 2.0% acetonitrile, 0.050% TFA in water; (B) 80% acetonitrile, 0.050% TFA in water; linear gradient, 0–40% B in 30 min, 40–100% B in 10 min; flow rate,  $1.7 \mu\text{L min}^{-1}$ ; temperature,  $50^\circ\text{C}$ ; detection, UV, 214 nm; sample, tryptic digest of 1.0 pmol of human transferrin. (Reprinted with permission from Premstaller *et al.* (2001) *Analytical Chemistry* 73: 2392–2394; © 2003 American Chemical Society.)

amounts (lower femtomole range) of tryptic peptides of human transferrin (Figure 3), bovine catalase (Figure 4), standard proteins (Figure 5), as well as membrane proteins from the photosystem II of higher plants.

Similarly, Huang *et al.* reported the separation of standard proteins, tryptic digests of cytochrome *c*, and myoglobin on both macroporous underivatized and octadecylated PS/DVB monoliths.

Hjerten's research group described the very fast separations (less than 100 s) of standard proteins and peptides on acrylamide-based monolithic capillary columns derivatized with  $\text{C}_{18}$  ligands.

Schenk *et al.* reported the quantification of cytokines in cell extracts using micro-HPLC packed microcolumns coupled with immunochemical detection. Various types of chromatographies were associated with the immunochemical detection system in order to perform the separation of cytokines. These included cation-exchange, size exclusion, and reversed-phase chromatography, with the latter being the most successful.

### Nucleic Acids

Huber's research group reported the rapid and highly efficient (efficiencies of up to 190 000 plates per

**Figure 4** Separation and mass analysis of tryptic peptides of bovine catalase. Column, monolithic PS/DVB,  $60 \times 0.20$  mm i.d.; mobile phase: (A) 0.050% TFA in water; (B) 80% acetonitrile, 0.050% TFA in water; linear gradient, 2–60% B in 15 min; flow rate,  $1.8 \mu\text{L min}^{-1}$ ; temperature,  $50^\circ\text{C}$ ; scan,  $m/z$  400–2000; electrospray voltage, 4.0 kV; sample, 5 pmol of tryptic digest of bovine catalase. meter) separations of single-stranded oligodeoxynucleotides and double-stranded DNA fragments by ion-pair reversed-phase micro-HPLC on PS/DVB monoliths (Figure 6) and conventional capillary columns packed with micropellicular octadecylated PS/DVB particles. The coupling with ESI-MS allowed the high resolution and identification of very small quantities of samples (femtomole amounts).

Simek *et al.* described the analysis and quantification of the purine bases hypoxanthine, xanthine, and guanine in excreta of ticks using a traditional reversed-phase  $\text{C}_{18}$  packed microcolumn.

### Agrochemicals

Cappiello's research group applied micro-HPLC to the screening of water samples for pesticide contamination. With electron ionization mass spectrometric detection and the use of two microcolumns packed with a  $\text{C}_{18}$  silica-based stationary phase, they performed the preconcentration of water samples and successfully detected trace levels of pollutants in similar samples. They also showed that ion-interaction micro-HPLC on a  $\text{C}_{18}$  stationary phase with hexylamine as the ion-pair reagent and coupling to particle beam mass spectrometry could be successfully used for the analysis of herbicides ranging from acidic species such as

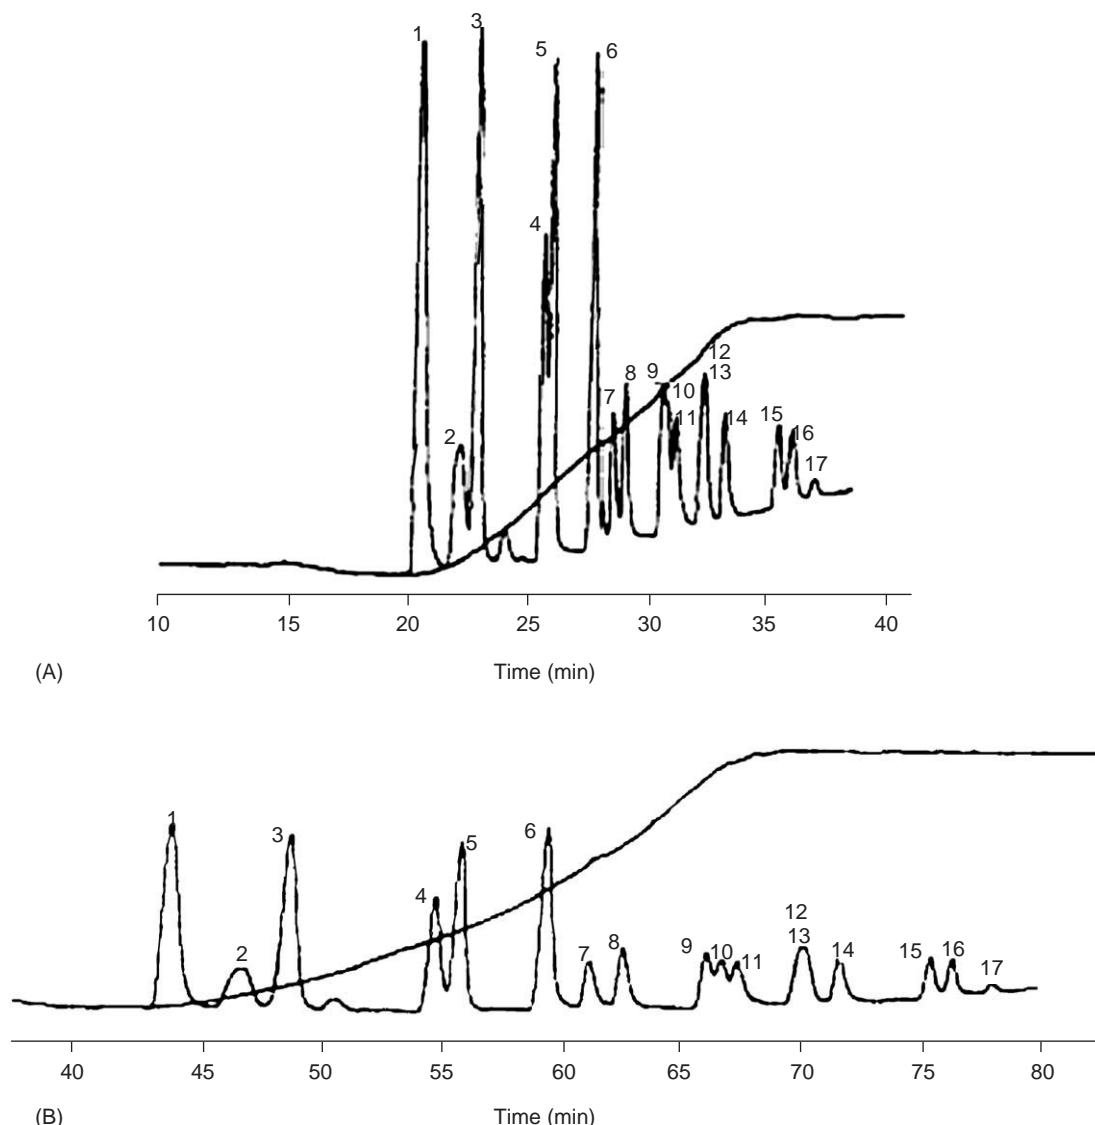

**Figure 6** High-resolution capillary IP-RP-HPLC separation of phosphorylated oligodeoxynucleotide ladders in a monolithic capillary column. Column, continuous PS/DVB,  $60 \times 0.20$  mm i.d.; mobile phase: (A)  $100 \text{ mmol L}^{-1}$  TEAA, pH 6.97; (B)  $100 \text{ mmol L}^{-1}$  TEAA, pH 6.97, 20% acetonitrile; linear gradient, (a) 15–45% B in 3.5 min, 45–55% B in 2.5 min, 55–65% B in 4.0 min; flow-rate,  $2.5 \mu\text{L min}^{-1}$ ; temperature,  $50^\circ\text{C}$ ; detection, UV, 254 nm; sample,  $\text{p(dA)}_{12-18}$ ,  $\text{p(dT)}_{12-30}$ , 40–98 fmol of each oligodeoxynucleotide. (Reprinted with permission from Premstaller *et al.* (2000) *Analytical Chemistry* 72: 4388; © 2003 American Chemical Society.)

phenoxy acids, to weak basic species such as phenol ureic herbicides, in a single analysis. An example of the separation of 17 acidic pesticides is featured in Figure 7.

Collins *et al.* described the ultrafast (less than 1 min) separations of triazine herbicides and benzodiazepines on sol-gel bonded continuous beds filled with large pore octadecylsilica particles coupled with time-of-flight mass spectrometric detection. Efficiencies of up to 50 000 plates per meter were achieved with the benzodiazepines.

#### Other Aromatic Compounds: PAHs and Alkylbenzenes

Maruska *et al.* described the separations of polar aromatic solutes such as pyridine, 4-pyridylmethanol, 4-methoxyphenol, 2-naphthol, catechol, hydroquinone, resorcinol, and 2,7-dihydroxynaphthalene by normal-phase micro-HPLC on acrylic polymer-based continuous beds as illustrated in Figure 8. Efficiencies of up to 150 000 plates per meter were achieved on columns II and III, which only differ by their monomer composition.

**Figure 7** Chromatographic separation of 17 acidic pesticides obtained injecting 50  $\mu\text{L}$  of aqueous sample in different injection mode: (A) excluding and (B) including the loop in the mobile phase path after completion of the injection process. Chromatographic conditions: (water + 0.05% TFA)–(methanol + 0.025% TFA), 100:0 to 20:80 in 40 min; flow rate, 2  $\mu\text{L min}^{-1}$ ; sample concentration, 1  $\text{ng } \mu\text{L}^{-1}$ . UV detection of pesticides was performed at 225 nm. UV detection of mobile phase concentration (solid line) was performed at 190 nm. 1 = Picloram, 2 = 4-nitrophenol, 3 = Chloramben, 4 = 2,4-dinitrophenol, 5 = Dicamba, 6 = Bentazone, 7 = 2,4-D, 8 = MCPA, 9 = Mecoprop, 10 = Dichlorprop, 11 = 2,4,5-T, 12 = 2,4-DB, 13 = MCPB, 14 = 2,4,5-TP, 15 = Dinoseb, 16 = Dinoterb, 17 = pentachlorophenol. **Figure 8** Normal-phase capillary chromatography of polar aromatic compounds: pyridine (1), 4-pyridylmethanol (2), 4-methoxyphenol (3), 2-naphthol (4), catechol (5), hydroquinone (6), resorcinol (7), 2,7-dihydroxynaphthalene (8). UV detection at 220 nm. (A) Column II, mobile phase: hexane–ethanol–methanol, pressure: 62 bar; (B) Column II, mobile phase: pure methanol, pressure: 56 bar; (C) Column III, mobile phase: pure methanol, pressure: 5 bar. Column II: 100  $\mu\text{m}$  i.d., 125 mm effective length, 175 mm total length, manufactured from a polymerization mixture containing 300 mg *N*-isopropylacrylamide, 50 mg methacrylamide, 125 mg piperazine diacrylamide, and 10 mg ammonium persulfate dissolved in 1 ml of 50  $\text{mol l}^{-1}$  sodium phosphate, pH 7. Column III: 100  $\mu\text{m}$  i.d., 126 mm effective length, 174 mm total length, manufactured from a polymerization mixture containing 180 mg 2-hydroxyethyl methacrylate, 5 mg vinylsulfonic acid, 150 mg piperazine diacrylamide, and 50 mg ammonium persulfate dissolved in 1 ml of 50  $\text{mol l}^{-1}$  sodium phosphate, pH 7. (Reprinted with permission from Maruska *et al.* (1999) *Journal of Chromatography A* 1837: 25–33; © 2003 Elsevier.)

Ericson *et al.* described the separation of a series of PAHs (naphthalene, 2-methylnaphthalene, fluorine, phenanthrene, and anthracene) on a 25  $\mu\text{m}$  i.d. continuous bed with  $\text{C}_{18}$  ligands and immobilized dextran sulfate. Efficiencies of up to 105 000 plates per meter were obtained.

Tanaka's research group reported the analysis of a series of alkylbenzenes ( $\text{C}_6\text{H}_5-(\text{CH}_2)_n\text{H}$ ,  $n=0-6$ ) and PAHs (naphthalene, fluorine, phenanthrene, anthracene, pyrene, triphenylene, and benzo[*a*]pyrene) on tetramethoxysilane-based macroporous silica gel monoliths and achieved efficiencies up to 80 000 plates per meter.

Tang *et al.* successfully performed the separation of aromatic standards and aromatic amines on

monolithic columns containing sol-gel bonded octadecylsilica particles.

At present, micro-HPLC is not widely used despite its obvious advantages. For years, the lack of suitable instrumentation/hardware inhibited the use of micro-HPLC. Modification of conventional equipment helped kick-start the technique but the lack of suitable hardware (injectors/capillary columns) still prevented its widespread use. These issues have been addressed in the laboratories of micro-LC practitioners in academia and industry and by a few commercial suppliers. However, there still remains a perception that micro-LC is difficult to perform and therefore the exciting advantages of the technique go unrealized by many in the separation sciences. With

the advance in instrumentation and the successful manufacture of robust capillary columns, it is believed that the technique is going to expand and within a few years may become the dominant technique of choice for analysis.

This article is a revision of the previous-edition article by J-L Rocca, pp. 2579–2584, © 1995, Elsevier Ltd.

## Introduction

In liquid chromatography (LC), solute retention is governed by the solute distribution factor, which reflects the different interactions of solute–stationary phase, solute–mobile phase, and mobile phase–stationary phase. For a given stationary phase, the retention of given solutes depends directly on the mobile phase, the nature and composition of which have to be judiciously selected in order to get the appropriate solute retentions and the required solute separation. The mobile phase has to be adapted in terms of elution strength (solute retention) and solvent selectivity (solute separation). This adaptation of the solvent requires some preliminary experiments, and, according to the complexity of the mobile phase that is to be optimized, the use of manual or computer-based optimization procedures needs to be considered. Hundreds of solvents are available to the chromatographer for use as mobile phase components. Solvent properties that relate to detection, miscibility (mobile phases prepared for high-performance liquid chromatography analyses

must be miscible, preferably at all proportions), viscosity, and purity are all important considerations.

## Solvent Polarity

Polarity is a key word in many chromatographic separations since a polar mobile phase will give rise to a low solute retention in normal phase LC (liquid–solid chromatography, LSC, of adsorption chromatography), or to a high solute retention in reversed–phase LC (RPLC). Nevertheless, it is often unclear exactly what this term means. One way to define the concept of polarity is to consider the Hildebrand solubility parameter; another is to consider the Snyder solvent parameter.

### Hildebrand's Solubility Parameter

Hildebrand has defined a regular solution in which deviations from ideality are attributed only to the enthalpy of mixing, the intermolecular forces being dispersion forces. The equation describing this model is

$$\Delta H_{\text{mix}} = \varphi_S^2 V_A (\delta_S - \delta_A)^2 \quad [1]$$

where  $\varphi_S$  is the volume fraction of the solvent,  $V_A$  is the molar volume of solute A, and  $\delta_S$  and  $\delta_A$  are the so-called solubility parameters for the solvent and the solute, respectively, measuring the internal

the advance in instrumentation and the successful manufacture of robust capillary columns, it is believed that the technique is going to expand and within a few years may become the dominant technique of choice for analysis.

## Introduction

In liquid chromatography (LC), solute retention is governed by the solute distribution factor, which reflects the different interactions of solute–stationary phase, solute–mobile phase, and mobile phase–stationary phase. For a given stationary phase, the retention of given solutes depends directly on the mobile phase, the nature and composition of which have to be judiciously selected in order to get the appropriate solute retentions and the required solute separation. The mobile phase has to be adapted in terms of elution strength (solute retention) and solvent selectivity (solute separation). This adaptation of the solvent requires some preliminary experiments, and, according to the complexity of the mobile phase that is to be optimized, the use of manual or computer-based optimization procedures needs to be considered. Hundreds of solvents are available to the chromatographer for use as mobile phase components. Solvent properties that relate to detection, miscibility (mobile phases prepared for high-performance liquid chromatography analyses

must be miscible, preferably at all proportions), viscosity, and purity are all important considerations.

## Solvent Polarity

Polarity is a key word in many chromatographic separations since a polar mobile phase will give rise to a low solute retention in normal phase LC (liquid–solid chromatography, LSC, of adsorption chromatography), or to a high solute retention in reversed–phase LC (RPLC). Nevertheless, it is often unclear exactly what this term means. One way to define the concept of polarity is to consider the Hildebrand solubility parameter; another is to consider the Snyder solvent parameter.

### Hildebrand's Solubility Parameter

Hildebrand has defined a regular solution in which deviations from ideality are attributed only to the enthalpy of mixing, the intermolecular forces being dispersion forces. The equation describing this model is

$$\Delta H_{\text{mix}} = \varphi_S^2 V_A (\delta_S - \delta_A)^2 \quad [1]$$

where  $\varphi_S$  is the volume fraction of the solvent,  $V_A$  is the molar volume of solute A, and  $\delta_S$  and  $\delta_A$  are the so-called solubility parameters for the solvent and the solute, respectively, measuring the internal

pressure of the corresponding substances. This solubility parameter is defined as the square root of the cohesive energy density according to

$$\delta = (-E/V)^{1/2} \quad [2]$$

where  $E$  is the cohesive energy and  $V$  is the molar volume,  $\delta$ , commonly expressed in  $\text{J}^{1/2}\text{ml}^{-1/2}$  or  $\text{cal}^{1/2}\text{ml}^{-1/2}$  is a measure of the interactive forces between molecules. The stronger the intermolecular interaction, the more effectively the compound acts as a solvent for polar solutes. Table 1 gives the solubility parameter of some compounds of chromatographic interest.

Chromatographers have used this solubility parameter to predict chromatographic retention in gas chromatography and in LC. Assuming that both phases, stationary and mobile, are bulk fluids (i.e., LC), the retention factor  $k_i$  of a solute is related to solubility parameters according to

$$\ln k_i = (V_i/RT)(\delta_m + \delta_x - 2\delta_i)(\delta_m - \delta_x) + \ln(n_x - n_m) \quad [3]$$

where  $\delta_m$ ,  $\delta_x$ , and  $\delta_i$  are the solubility parameters of the mobile phase, the stationary phase, and the solute, respectively. Consequently, in RPLC,  $\delta_m$  being larger than  $\delta_x$ , a mobile phase possessing a large solubility parameter will give rise to high solute retention. The elution strength of a mobile phase varies as the inverse of its solubility parameter. In LSC,  $\delta_m$  being lower than  $\delta_x$ , the elution strength of mobile phases varies according to their solubility parameters.

To a first approximation, the solubility parameters for mixed mobile phases can be written as

$$\delta_m = \Sigma \varphi_i \delta_i \quad [4]$$

where  $\varphi_i$  is the volume fraction of component  $i$  in the mixture, possessing the solubility parameter  $\delta_i$ . For a binary mixture of water ( $w$ ) and an organic modifier

(a), the solubility parameter is expressed as

$$\delta_m = \varphi_w \delta_w + \varphi_a \delta_a \quad [5]$$

and because  $\varphi_w + \varphi_a = 1$ , eqn [5] becomes

$$\delta_m = \delta_w + \varphi_a(\delta_a - \delta_w) \quad [6]$$

In RPLC, by considering eqn [5] and the  $\delta_a$  values from Table 1, to a first approximation, it may be expected that mixtures of the same solubility parameter will yield the same solute retention factor. In other words, if acetonitrile (ACN) or tetrahydrofuran (THF) is used instead of methanol (MeOH) in a binary mixture with water, a composition of  $\varphi_{\text{ACN}} = 0.78\varphi_{\text{MeOH}}$  or  $\varphi_{\text{THF}} = 0.62\varphi_{\text{MeOH}}$  is expected to yield roughly the same retention factor as the composition  $\varphi_{\text{MeOH}}$ .

Combining eqns [3] and [6] we find

$$\ln k_i = A\varphi_x^2 + B\varphi_a + C \quad [7]$$

where  $A$ ,  $B$ , and  $C$  are constants in the chromatographic system.

### Snyder's Solvent Parameter

According to the model of adsorption in LSC provided by Snyder, the solute distribution constant  $K$  is given by

$$\log K = \log V_a + E_a(S^0 - A_s \varepsilon^0) \quad [8]$$

where  $V_a$  is the adsorbent surface volume,  $E_a$  is the average surface activity of the adsorbent,  $S^0$  is the adsorption energy of the solute,  $A_s$  is the area of solid adsorbent required by the adsorbed solute, and  $\varepsilon^0$  is the Snyder eluent strength parameter. Relative partition coefficients obtained with two different mobile phases for a given solute and a given stationary phase are given by

$$\log(K_2 - K_1) = E_a A_s (\varepsilon_1^0 - \varepsilon_2^0) \quad [9]$$

**Table 1** Solubility parameters and partial solubility parameters (expressed in  $\text{cal}^{1/2}\text{ml}^{-1/2}$ ) for some compounds

Compound	$\delta_t$	$\delta_d$	$\delta_a$	$\delta_{ird}$	$\delta_a$	$\delta_b$
Water	25.52	7.2	—	—	21.7	14.2

The ratio of the distribution factors obtained with the two mobile phases depends on their difference in eluent strength ( $\epsilon_1^0 - \epsilon_2^0$ ) since  $E_a$  and  $A_s$  are constant. By definition,  $\epsilon^0$  has a value of zero for *n*-pentane, and consequently the eluent strength parameters  $\epsilon^0$  were determined for different solvents: the larger the value of  $\epsilon^0$ , the less retained is a solute by that solvent. Table 2 illustrates some eluent strength parameter for alumina ( $\text{Al}_2\text{O}_3$ ) as the stationary phase, given that

$$\epsilon^0(\text{silica}) = 0.77\epsilon^0(\text{alumina}) \quad [10]$$

For the elution strength of a binary mobile phase, a mixture of solvents 1 and 2, having  $\epsilon_1^0$  and  $\epsilon_2^0$  as the respective eluent strengths and knowing that component 2 is the more strongly sorbed component, Snyder obtained the following relationship:

$$\epsilon_{12}^0 = \epsilon_1^0 + [\log(X_2 10^W (\epsilon_2^0 - \epsilon_1^0) + 1 - X_2)] / W \quad [11]$$

with  $W = E_A S_2$ , where  $E_A$  is the activity of the adsorbent,  $S_2$  is the area occupied by solvent 2 of the mobile phase, and  $X_2$  is the mole fraction of solvent 2. Figure 1 illustrates the elution strengths of some binary mobile phases, with silica as stationary phase.

## Solvent Selectivity

Although the solubility parameters or the solvent strength parameters are useful for quantifying the polarity of a mobile phase, they characterize only global interactions of mobile phases with solutes and stationary phases. The concepts have been refined by considering the different types of interaction that together contribute to interactions between species.

Interactions can be classified as follows:

- Dispersion interactions, which arise from the mutual interaction of the electron clouds of interacting species: all compounds, polar or nonpolar, exhibit such a dispersion interaction.
- Dipole orientation between molecules possessing as permanent dipole moment.
- Induced-dipole interactions, which occur when a permanent dipole induces a temporary dipole in a neighboring molecule.
- Acid–base interactions including all the processes in which electrons or protons are exchanged between molecules.

## Partial Solubility Parameter

Considering the different kinds of interaction, the solubility parameter can be written as a function of partial solubility parameters as

$$\delta_r^2 = \delta_d^2 + \delta_a^2 + 2\delta_{ms}\delta_d + 2\delta_a\delta_b \quad [12]$$

**Figure 1** Eluent strength ( $\epsilon^0$ ) of mixed solvents vs. the composition of a strong solvent in heptane. 1, Diisopropyl ether; 2, methylene chloride or chloroform; 3, ethyl acetate or acetone; 4, tetrahydrofuran or acetonitrile.

**Table 2** Eluent strength parameters,  $\epsilon^2$ , polarity index, and selectivity parameters for some classical solvents

Solvent	$\epsilon^0$ (alumina)	$P'$	$X_c$	$X_d$	$X_n$	Group
<i>n</i> -Hexane	0.00	0.1	—	—	—	
Toluene	0.22	2.4	0.25	0.28	0.47	VIII
Benzene	0.25	2.7	0.23	0.32	0.45	VIII
Diethyl ether	0.29	2.8	0.53	0.13	0.34	I
Methylene chloride	0.32	3.1	0.29	0.18	0.53	V
Isopropanol	0.63	3.9	0.55	0.19	0.27	II
Tetrahydrofuran	0.35	4.0	0.38	0.20	0.42	III
Chloroform	0.31	4.1	0.25	0.41	0.33	VIII
Ethanol	0.68	4.3	0.52	0.19	0.29	II
Ethyl acetate	0.45	4.4	0.34	0.23	0.43	VI
Dioxane	0.43	4.8	0.36	0.24	0.40	VI
Acetone	0.43	5.1	0.35	0.23	0.42	VI
Methanol	0.73	5.1	0.48	0.22	0.31	II
Acetonitrile	0.50	5.8	0.31	0.27	0.42	VI
Nitromethane	0.49	6.0	0.28	0.31	0.40	VII
Water	Large	10.2	0.37	0.37	0.25	VIII

where the subscripts refer to total (T), dispersion (d), orientation (o), induction (ind), acid (a), and base (b). Two different types of terms appear in eqn [12], viz. quadratic terms for dispersion and orientation interactions, which are symmetrical, and double product terms for induction and acid–base interactions, which are nonsymmetrical because the two molecules involved in the mutual interaction are not equivalent. Looking at Table 1, a distinction can now be made between solvents of similar overall polarity (similar total solubility parameter).

### Snyder Solvent Classification Scheme

Another way of classifying solvents in terms of their polarity and specific chemical interactions is the empirical scheme proposed by Snyder and based on experimental measurements of test solutes (probes) in gas–liquid chromatography, using LC mobile phases as stationary phases. The retention of probes reflects their interaction with the liquid stationary phase, so by selecting probes with selective interactions, Snyder could determine a set of numbers that characterized the liquids studied. Distribution constants were corrected for dispersion interactions and molecular weight effects ( $K^w$ ), and, assuming that there are three additive interaction (proton donor, proton acceptor, and strong dipole interactions), the distribution constants corrected for the three effects should sum to a total value called the polarity index  $P'$  defined according to

$$P' = \log(K^w)_d + \log(K^w)_e + \log(K^w)_n \quad [13]$$

where subscripts d, e, and n refer to these three interactions, respectively. Selecting dioxane, ethanol, and nitromethane as probes for measuring the proton donor effect, proton acceptor effect, and strong dipole effect, respectively,  $P'$  values were determined for the main solvents classically used in LC. Defining for each interaction a parameter such as

$$x_i = \log(K^w)_i / P' \quad [14]$$

$x_i$  will represent a selectivity parameter for measuring the proton donor character ( $i = d$ ), the proton acceptor character ( $i = e$ ), and the strong dipole character ( $i = n$ ). The sum of the three parameters is thus normalized to 1. Polarity index and selectivity parameters for some solvents are listed in Table 2. Using this approach, solvents that are chemically similar yield similar selectivity parameters, but solvents that are chemically different may appear in a single selectivity group. Some discrepancies can occur between the solvent classification according to the solubility parameters and to the polarity

index: acetonitrile, for example, appears as more polar than methanol in Table 2, whereas the reverse order is observed in Table 1. Nevertheless, this classification of solvents is very useful as the selectivity of solvent can be depicted in a triangular diagram because the sum of the selectivity parameters is equal to 1. Figure 2 illustrates such a representation: solvents can be classified into eight main classes; a summary of the resulting classification is given in Table 3.

To use the selectivity parameters in selecting solvent mixtures for LC, Snyder assumes that the mixture polarity is given by

$$P'_{AB} = (V_A/V_B)P'_A + (V_B/V_A)P'_B \quad [15]$$

The solvents A and B should be from two of the eight solvent groups in Figure 2 and should be as different as possible. The best solvents to be used are

- In LSC: diethyl ether (or methyl *t*-butyl ether), methylene chloride (dichloromethane), and chloroform from groups I, V, and VIII, respectively, the nonpolar solvent being hexane.
- In RPLC: methanol, acetonitrile and tetrahydrofuran from groups 2, 6, and 3, respectively, the polar solvent being water.

### Solvent Viscosity

Solvent viscosity affects the pressure drop across a column and dictates the flow rate. For nonaqueous mobile phase component mixtures, the viscosity ( $\eta$ ) can be estimated from the viscosity of the individual A and B solvents ( $\eta_A$  and  $\eta_B$ ) and their mole fractions

**Figure 2** Solvent classification according to Snyder. (Reproduced with permission from Snyder LR (1978) Classification of the solvent properties of common liquid. *Journal of Chromatogr. Sci.* 16: 223–234; © Preston Publications Division.)

**Table 3** Solvent classification according to Snyder (see Figure 2)

Group	Solvents
I	Aliphatic ethers Trialkylamines (somewhat more basic than group I solvents)
II	Aliphatic alcohols
III	Pyridine derivatives, THF, sulfoxides
IV	Glycols, acetic acid
V	Methylene chloride (dichloromethane), 1,2-dichloroethane
VI	a: Aliphatic ketones and esters, dioxane b: Sulfones, nitriles
VII	Aromatic hydrocarbons, halosubstituted aromatic hydrocarbons, nitro compounds, aromatic ethers
VIII	Fluoroalknols, water Chloroform (somewhat less basic than group VIII solvents)

( $x_A$  and  $x_B$ ):

$$\log(\eta) = x_A \log(\eta_A) + x_B \log(\eta_B) \quad [16]$$

Viscosity also decreases with temperature. Equation [16] does not hold for aqueous mobile phases as a result of the strong interactions between water molecules. For aqueous mobile phases, and temperature effects see Snyder (in the Further reading section).

### Detection

In LC, a means of detection is employed for identification and quantification. While detection is covered elsewhere in this volume, mobile phase selection can play an important role in the detectability of the compounds of interest, and vice versa. A solvent's lowest usable (cutoff) wavelength is important for UV detectors, solvent refractive index (RI) effects the sensitivity of RI detection, and solvent volatility is an important consideration for evaporative light scattering and mass spectrophotometric based detectors. Table 4 lists some common LC mobile phase spectral data.

## Solvent Optimization

The use of optimization methods makes it possible to separate complex mixtures in a short analysis time with binary, ternary, or quaternary mobile phases. Only procedures concerning the optimization of selectivity are described in this section.

### Simultaneous Method of Optimization

In such methods, all the experiments that have to be performed are defined in a first step. After all the corresponding chromatograms have been recorded,

the optimum can be located. This grid search requires that the entire parameter space is covered, usually at regular intervals. If two isoeluotropic solvents are selected (ternary mixtures) there is only one degree of freedom, i.e., one parameter. In this case, intervals of 10% lead to 11 experiments. For three isoeluotropic solvents (quaternary composition), the parameter space is located in an equilateral triangle because the sum of the solvent volume fractions is equal to 1: intervals of 10% require 66 experiments. Consequently, such a procedure is very time consuming; no effort of computation is required but complete automation of the method is recommended and is easily possible.

### Sequential Method of Optimization

This optimization procedure, based on the simplex technique, requires a number of initial experimental conditions that is one more than the number of parameters considered. The resulting chromatograms are qualified and the worst conditions corresponding to a given location inside the parameter space are replaced by new conditions (new location), and the process is repeated until the quality of the latest chromatogram does not differ from the quality of the preceding one. This procedure does not require any chromatographic model but does require a large number of experiments and may lead to only a local optimum.

### Interpretive Methods

Interpretive methods involve a given set of pre-planned experiments from which chromatographic results are used for predicting retention surfaces of individual solutes according to given mathematical or statistical models. The model for the retention surfaces of individual solutes is then used to calculate the response surface over the parameter space explored, and to locate the optimum.

**Window diagram** Window diagrams, developed by Laub and Purnell for optimizing the composition of mixed stationary phases in gas chromatography, can be used for optimizing mobile phase composition in LC. From two initial experiments (if a linear relationship is assumed between  $\log k$  and mobile phase composition) or more (in the case of a quadratic relationship), the retention models are calculated for all solutes, and a response function (selectivity between every possible pair of solutes) is calculated and plotted versus the mobile phase composition. Areas or windows in which all solutes are separated can be located graphically. No particular effort of computation is required in such a procedure.

**Table 4** Mobile phase spectral data

**Critical band method** The same development is adopted to determine the retention models for all solutes. Below every retention surface it is possible to determine a forbidden zone (critical band): any solute whose retention would fall into a critical band would interfere with the compound considered with a resolution value ( $R_S$ ) lower than a threshold value. The separation with  $R_S$  value higher than the threshold value is achieved at a composition for which none of the critical bands overlap. This is a graphical method for the optimization of a single parameter, such as the composition of a binary mobile phase or of a ternary mobile phase constituted of mixtures of two isoelutropic binary mobile phases.

**Overlapping resolution mapping** This method was developed by Glajch *et al.* for the optimization of quaternary mobile phase composition in LSC or in RPLC. The first step is to restrict the parameter space to isoelutropic solvents corresponding to the appropriate  $k$  value for the last-eluted solute. In such a way, the parameter space is defined by an equilateral triangle, the three apices of which correspond to binary mobile phases, and the three sides to ternary mobile phases. Any composition inside the triangle is a quaternary mobile phase composition. Seven experiments, corresponding to the composition of each apex, the composition of each half-side, and the composition of the center of the triangle, are carried

out. The surface retention of each solute is characterized by a quadratic model, the coefficients of which are determined by regression analysis. The response surface (threshold minimum resolution) is calculated by means of the retention models: the overlapping resolution mapping procedure consists of eliminating zones inside the triangle that correspond to  $R_s$  values lower than the threshold value and repeating the procedure for all pairs of solutes. The remaining zones inside the triangle will define the optimized compositions of the mobile phase. This method is relatively fast and simple, and may be automated. Nevertheless, more experiments may be required if a more accurate description of the response surface around the optimum is required.

### Iterative Methods

Iterative methods are interpretive methods in which new experiments can be added to the small number of starting experiments in order to refine the surface retention for all the solutes, and to predict more accurately the optimum location in the parameter space. For single-parameter optimization both graphical and mathematical methods can be used, but for multiparameter optimization computerized methods are necessary.

### Gradient Elution

In most cases, solute separations can be achieved in the isocratic mode by optimizing the mobile phase composition. Nevertheless, for some complex cases of solutes possessing very different polarities, separations can require a gradient elution mode: in such cases, mobile phase compositions and gradient slopes have to be determined.

For a chromatographic experiment carried out in gradient elution mode, the composition of the mobile phase is varied during the analysis. This is achieved by a gradual increase of the proportion of methanol, acetonitrile, or tetrahydrofuran in water for RPLC, or of diisopropyl ether, methylene chloride, or chloroform in *n*-hexane for LSC. During such a programmed analysis, solutes of a wide range of polarities can be eluted from the column under optimum conditions in a single experiment. According to the concept of linear solvent strength (LSS) gradients developed by Snyder, the shape of an LSS gradient is given by

$$\log k_m = \log k_a - b(t/t_0) \quad [17]$$

where  $k_m$  is the capacity factor of the solute under the isocratic conditions at the column inlet at time  $t$ ,  $k_a$  is the capacity factor of the solute at the initial composition of the gradient program,  $b$  is the

gradient steepness of the gradient,  $t$  is the time elapsed since the arrival of the starting gradient at the column inlet, and  $t_0$  is the column dead time. Optimized  $b$  values range from 0.2 to 0.4.

In LSC, according to eqns [8] and [11], an LSS gradient is concave. In RPLC, eqn [7] can be simplified into a linear relationship between  $\ln k$  and  $\varphi$ :

$$\ln k = \ln k_0 - S\varphi \quad [18]$$

with  $5 < S < 10$  for low molecular mass solutes in water-methanol mixtures. Consequently, in RPLC, an LSS gradient is given by a linear gradient such as

$$\varphi = A + Bt \quad [19]$$

Considering eqns [16]–[18], it appears that the optimum gradient slope  $B$  expressed in  $\text{min}^{-1}$  is given by

$$B = 2.303b/(St_0) \quad [20]$$

Initial conditions of gradient can be optimized by a trial-and-error approach in such a way that solutes are eluted neither too late nor too early during the analysis. Not only are many complex samples better separated in a gradient elution mode, but gradient runs can also be used to predict the relationship between retention of solutes and mobile phase composition in the isocratic mode.

Additional considerations in the choice of whether or not to use gradient mobile phases include:

- It requires an instrument capable of generating gradients.
- Because of differences in instrumentation, method transfer and validation can be more problematic than for isocratic methods.
- Some detection methods are not compatible.
- Mobile phases need to be sparged or degassed due to bubble formation when mixing aqueous and organic phases.
- Baseline shifts may be encountered due to UV absorbing modifiers.

### Buffered Mobile Phases

For the reversed phase separation of acidic or basic compounds, it is strongly recommended to include a buffer to control the pH of the mobile phase. Capacity, UV absorbance, volatility, solubility, stability, and sample and stationary phase interaction are important to consider when selecting a buffer. For reversed phase separation, a buffer concentration in the range of  $10\text{--}50 \text{ mmol l}^{-1}$  is usually sufficient, when used within  $\pm 1.0$  pH units of the  $\text{p}K_a$ . Stationary phases recently introduced to the market easily withstand exceedingly higher pH, allowing

the chromatographer to use pH as a true selectivity tool.

## Introduction

Normal-phase liquid chromatography (NPLC) is the oldest chromatographic mode, discovered by M.S. Tswett more than 100 years ago. It has been the predominant mode in thin-layer chromatography (TLC) and low-pressure dry-column liquid chromatography before the introduction of reversed-phase technique, which is a preferred mode in high-performance liquid chromatography (HPLC).

In normal-phase chromatography, the stationary phase is more polar than the mobile phase. As illustrated in **Figure 1**, the retention increases as the polarity of the mobile phase decreases and thus polar analytes are more strongly retained than nonpolar analytes, the opposite of that in reversed-phase liquid chromatography (RPLC). The column packing is either an inorganic adsorbent (silica gel or, less often, aluminum, titanium, or zirconium oxides) or a moderately polar bonded phase (cyanopropyl,  $-(CH_2)_3-CN$ ; diol,  $-(CH_2)_3-O-CH_2-CHOH-CH_2-OH$ ; or aminopropyl,  $-(CH_2)_3-NH_2$ ) chemically bonded on a suitable support material, which is usually silica gel. The mobile phase is usually a mixture of two or more organic solvents: nonpolar solvent and strongly or weakly polar solvents.

Moderately polar bonded phases may be used either in the normal-phase mode with organic mobile phases, such as *n*-hexane + 2-propanol, or in the reversed-phase mode with aqueous–organic mobile phases (**Figure 2**). However, normal-phase behavior can also be sometimes observed in nonaqueous

RPLC with chemically bonded C18, C8, or other alkyl-bonded phases. The reason is the activity of polar residual silanol groups that remain on the support surface after incomplete reaction of silica gel with organosilanes. Thus, such a stationary phase may behave as a deactivated polar adsorbent in nonpolar or weakly polar organic solvents.

**Figure 1** Schematic diagram of the effects of sample and mobile phase polarities on the retention in normal-phase (NP) and reversed-phase (RP) liquid chromatography.  $V_R$  – retention volume.

the chromatographer to use pH as a true selectivity tool.

## Introduction

Normal-phase liquid chromatography (NPLC) is the oldest chromatographic mode, discovered by M.S. Tswett more than 100 years ago. It has been the predominant mode in thin-layer chromatography (TLC) and low-pressure dry-column liquid chromatography before the introduction of reversed-phase technique, which is a preferred mode in high-performance liquid chromatography (HPLC).

In normal-phase chromatography, the stationary phase is more polar than the mobile phase. As illustrated in **Figure 1**, the retention increases as the polarity of the mobile phase decreases and thus polar analytes are more strongly retained than nonpolar analytes, the opposite of that in reversed-phase liquid chromatography (RPLC). The column packing is either an inorganic adsorbent (silica gel or, less often, aluminum, titanium, or zirconium oxides) or a moderately polar bonded phase (cyanopropyl,  $-(\text{CH}_2)_3\text{-CN}$ ; diol,  $-(\text{CH}_2)_3\text{-O-CH}_2\text{-CHOH-CH}_2\text{-OH}$ ; or aminopropyl,  $-(\text{CH}_2)_3\text{-NH}_2$ ) chemically bonded on a suitable support material, which is usually silica gel. The mobile phase is usually a mixture of two or more organic solvents: nonpolar solvent and strongly or weakly polar solvents.

Moderately polar bonded phases may be used either in the normal-phase mode with organic mobile phases, such as *n*-hexane + 2-propanol, or in the reversed-phase mode with aqueous–organic mobile phases (**Figure 2**). However, normal-phase behavior can also be sometimes observed in nonaqueous

RPLC with chemically bonded C18, C8, or other alkyl-bonded phases. The reason is the activity of polar residual silanol groups that remain on the support surface after incomplete reaction of silica gel with organosilanes. Thus, such a stationary phase may behave as a deactivated polar adsorbent in nonpolar or weakly polar organic solvents.

**Figure 1** Schematic diagram of the effects of sample and mobile phase polarities on the retention in normal-phase (NP) and reversed-phase (RP) liquid chromatography.  $V_R$  – retention volume.

**Figure 2** Effects of the concentration of 2-propanol,  $\phi$ , in the mobile phase on the retention factors,  $k$ , of phenylurea herbicides on a bonded nitrile column in normal-phase (2-propanol/hexane) and reversed-phase (2-propanol-water) modes. Column: Silasorb Nitrile, 7.5  $\mu\text{m}$ , 300  $\times$  4.2 mm ID. Solutes: bis-*N,N*-(3-chloro-4-methylphenyl)urea (1); 2-*N*-butyl-*N'*-phenylurea (2); isoproturon (3); *N*-phenylurea (4); hydroxymethoxuron (5). (Adapted with permission from Fischer J and Jandera P (1994) *Journal of Chromatography A* 684: 77–92; © Elsevier.)

As the retention on inorganic adsorbents originates due to the interactions of the polar adsorption centers on the surface with the polar functional groups of the analytes, this mode was also called adsorption or liquid–solid chromatography.

## Practical Considerations

In the reversed-phase mode, higher separation selectivity than in normal-phase chromatography can be usually achieved for compounds with even minor differences in the size of the molecules. This is the main reason for the predominant role of reversed-phase separations in contemporary HPLC. On the other hand, NPLC usually offers significantly better separation of isomers than RPLC.

Normal-phase chromatography has several practical advantages: (1) Because of a lower organic mobile phase viscosity, the pressure drop across the column is lower than with aqueous–organic mobile phases commonly used in RPLC at a comparable flow rate. (2) HPLC columns are usually more stable and have longer lifetimes in organic solvents than in aqueous–organic mobile phases. (3) Columns packed with nonmodified inorganic adsorbents are not subject to ‘bleeding’, i.e., gradual loss of the chemically bonded stationary phase originating from hydrolysis, which slowly decreases the retention during the lifetime of a chemically bonded column, especially in aqueous mobile phases and at elevated temperatures.

(4) Many samples are more soluble or less prone to decompose in organic than in aqueous mobile phases. Such samples do not cause direct-injection problems in NPLC, unlike to RPLC. (5) The recovery of organic-soluble sample components is easy in preparative NPLC. (6) Very large changes in separation selectivity are possible by changing either the mobile phase or the stationary phases in NPLC.

On the other hand, reversed-phase chromatography generally offers better selectivity than NPLC for the separation of molecules differing in carbon number. Further, ionic samples are usually more easily separated in RPLC. The purchase and disposal of organic solvents are more expensive in NPLC than in RPLC, and lower-boiling solvents are more prone to evaporation and bubble formation, especially at elevated temperatures. Finally, controlling the retention by adjusting the solvent strength can be less predictable and reproducible in NPLC than in RPLC, because of significant preferential adsorption of polar solvents, especially water, on polar adsorbents.

## Principles of Retention in NPLC

In RPLC, the retained solute molecules are not localized on the surface of the column packing (this behavior resembles a partition process), whereas the adsorbed polar sample and solvent molecules in NPLC are localized on specific polar adsorption sites, to which they are strongly attracted. Neutral

compounds can be separated by both RPLC and NPLC, generally with the opposite order of elution, but some differences in the separation selectivity and elution order are usually observed between the two modes. This is illustrated in **Figure 2** for the retention factors,  $k$ , of some phenylurea herbicides on a bonded nitrile column in propanol–hexane (normal-phase mode) and propanol–water (reversed-phase mode) mobile phases.

The retention model in adsorption chromatography developed by Snyder and Soczewinski is based on the assumption that there is flat adsorption in a monomolecular layer on a homogeneous adsorption surface. The adsorption is understood as a competition phenomenon between the molecules of the solute and the solvent on the adsorbent surface, so that the retention of a sample molecule requires the displacement of one or more previously adsorbed polar solvent molecules. Later, the model was corrected for adsorption on a heterogeneous surface of adsorbent. To first approximation, the solute–solvent interactions in the mobile and stationary phases are assumed to compensate each other and possible liquid–liquid partition effects are neglected. In this case, the retention in a mixed binary mobile phase comprising a nonpolar solvent, A (usually an aliphatic hydrocarbon), and a polar solvent, B, can be described by eqn [1]:

$$\log k = \log k_a + \alpha' A_s (\epsilon_a - \epsilon_{ab}) \quad [1]$$

Here,  $k$  is the retention factor in a binary mobile phase containing solvents A and B, which can be calculated from the retention volume of the analyte,  $V_R$ , and the column hold-up volume,  $V_M$  (determined as the elution volume of a nonretained compound, such as trichloroethylene),  $k = V_R/V_M - 1$ ,  $k_a$  is  $k$  in pure weak solvent, A,  $\alpha'$  is the activity of the adsorbent in the column,  $A_s$  is the specific surface of the adsorbent, and  $\epsilon_a$  and  $\epsilon_{ab}$  are the solvent strength (polarity) parameters of the weak (nonpolar) solvent and of the mixed binary mobile phase, respectively.

The retention in NPLC increases with increasing polarity (activity) and is proportional to the specific surface area,  $A_s$ , which controls the number of the adsorption sites available for contact with the sample solutes in the column. Water in mobile phases deactivates the adsorbent (decreases  $\alpha'$ ), as the sites with strongly held adsorbed water are no longer available for adsorption of moderately polar organic compounds. The elution times of analytes generally increase in the following sequence: alkanes < alkenes < aromatic hydrocarbons  $\approx$  chloroalkanes < alkylsulphides < ethers < ketones  $\approx$  aldehydes  $\approx$  esters < alcohols < amides < phenols, amines, carboxylic acids. The

retention also depends to some extent on the hydrocarbon part of solutes and generally slightly decreases as the size of alkyl groups increases. However, the adsorption energy of alkyl groups is low and the adsorbed molecules adhere to the adsorbent surface by the polar groups, whereas the hydrocarbon parts of the molecules point from the adsorbent surface toward the mobile phase. The separation in a homologous series is far less effective than in reversed-phase chromatography and usually only a few lowest homologs can be successfully resolved by NPLC. If the localization of the adsorption sites on the surface of a polar adsorbent fits a spatial distribution of polar functional groups in a solute molecule with multiple functional groups, simultaneous interactions of two or more functional groups are possible, which are weaker or absent for molecules with other positions of functional groups. Hence, NPLC (especially on silica gel columns) is usually suitable for separation of positional isomers. Further, differences in the retention of molecules of similar polarities, but different shapes (rigid planar, rod-like, or of flexible chain structure), are often observed and utilized in normal-phase chromatography. Both steric hindrance to the access of a polar functional group to the adsorption site and interactions between vicinal polar groups decrease the adsorption and the retention. Hence, *ortho*-substituted benzenes are less strongly retained than *meta*- and *para*-isomers. For example, *o*-nitrophenol elutes earlier than *m*-nitrophenol, whereas *p*-nitrophenol is retained most strongly in NPLC because of increased acidity caused by mesomeric effect.

The retention decreases at increased temperature, but high temperatures are rarely used in NPLC because of relatively low boiling points of polar organic solvents. Usually, a change in temperature has only minor effects on the selectivity and band spacing in NPLC, except for mobile phases containing localizing solvents (e.g., acetonitrile), which are desorbed at elevated temperatures.

### Columns and Stationary Phases in NPLC

Nowadays, most HPLC separations are performed on conventional analytical columns, 10–25 cm long, 3–4.6 mm in diameter, and packed with 3–10  $\mu$ m uniform particles (recently even with 1–2  $\mu$ m size). With short ‘high-speed’ columns, 1.5–5 cm long, simple separations can be accomplished in 1–3 min, with significantly reduced analysis time and solvent consumption. Separations on ‘microbore’ columns, 15–25 cm long and 1–2 mm ID, need even less mobile phase and allow detection of high mass sensitivity. These columns are useful for analyses of small

sample amounts and with mass-spectrometric detection. Recently, packed capillary HPLC columns of internal diameter 0.1–0.5 mm have become commercially available. However, the microbore and especially the capillary columns need miniaturized instrumentation to suppress extracolumn contributions of the injector, the detector, and the connecting capillaries to band broadening.

NPLC stationary phases include metal oxides and moderately or strongly polar chemically bonded phases. Unmodified silica gel and silica-based bonded phases are most frequently used nowadays. Considerable effort in the development of new HPLC column packing materials in the past years has resulted in significant improvement of the column efficiency, reproducibility, and increased stability at elevated temperatures and at higher pH, enabling better compatibility with HPLC/mass spectrometry techniques and rapid analyses. Even though the new column technologies were primarily focused on RPLC separations, normal-phase HPLC also benefits from the improved properties of the support materials with uniform small particles and well-defined pore size.

Relatively inexpensive irregular shape materials are still used extensively for preparative separations. However, they are being gradually replaced by spherical particles in analytical HPLC, since they form more homogeneous, stable, and permeable column beds, requiring lower working pressures. Because of superior performance of spherical microparticles with diameters less than 5  $\mu\text{m}$ , irregular materials of this size are only rarely used, if at all. The porosity of particles suitable for packing HPLC columns depends on the size of the separated molecules. Totally porous particles with pore size 7–12 nm and specific surface area 150–400  $\text{m}^2 \text{g}^{-1}$  are suitable for separations of small molecules, but wide-pore particles with pore size 15–100 nm and relatively low specific surface area (10–150  $\text{m}^2 \text{g}^{-1}$ ) are required for HPLC of macromolecules to allow easy access to the interactive surface within the pores.

**Silica gel** Macroporous silica gel is the material most often used in NPLC and is also the most important support material for preparing chemically bonded phase packings with a large variety of functionalities. The main advantages of silica particles are their high mechanical strength, compatibility with water and all organic solvents, and dimensional stability of column beds during use with various solvent types and gradient elution, as the wet silica particles do not swell.

Noncrystalline silica has the general chemical formula  $\text{SiO}_2 \cdot x\text{H}_2\text{O}$ , in which  $x$  depends on the degree

of hydration. The unmodified hydrated silica contains a surface layer of  $-\text{SiOH}$  (silanol) groups with a maximum concentration of  $\sim 8 \mu\text{mol m}^{-2}$ . The silanol groups are free, vicinal (on two vicinal silicon atoms), or geminal (two  $-\text{SiOH}$  groups borne by the same silicon atom). Vicinal silanols may be associated by hydrogen bonds. In addition, siloxane bonds ( $-\text{Si}-\text{O}-\text{Si}-$ ) may be present on the silica surface. Silanol groups may be associated with water molecules by hydrogen bonding. By heating to 115–200°C, the silica surface is first dehydrated by removing the adsorbed water. Further heating up to 400°C causes associated silanols to reversibly condense to siloxanes and at higher temperatures, irreversible siloxane formation occurs connected with lattice rearrangement and sintering.

An unfavorable property of silica is its solubility at high pH, which, however, is rarely applied with the mobile phases used in NPLC. Silica gel has weak cation-exchange properties (the silanols on the silica gel surface may be ionized to  $\text{SiO}^-$  groups), whereas the bonded amine stationary phases behave as weak anion exchangers. This mixed retention mechanism may cause excessive retention and tailing or even split peaks of ionic or ionizable compounds.

Several technologies are used for preparation of silica gel for HPLC. ‘Sol-gel’ silica with irregular particles can be prepared by acidifying solutions of silicates (type A silicas) or by hydrolysis of tetraalkylsilanes and precipitation of a hydrosol, followed by aging, which results in gelling of the colloidal particles to form larger aggregates connected by siloxane bonds. After washing free of the residual sodium salts and crushing to the desired particle size, a hard, porous xerogel is produced. Spherical microparticles can be prepared by emulsification of a silica sol in a water-immiscible organic liquid. Type A silica gels are more or less acidic because of contamination with certain metals, which activate surface silanol groups and can complex with some chelating solutes, causing strong retention or asymmetrical peaks.

Newer, highly purified, less-acidic ‘sol-gel’ spherical silica particles (type B silicas) are formed by the aggregation of silica sols exposed to air, contain very low amounts of metals and are more stable at intermediate and higher pH than the xerogel-type materials, to at least pH 9. They generally provide better separations, especially of basic samples. Recently, silica gel with a surface populated with nonpolar silicon hydride  $\text{Si}-\text{H}$  groups instead of silanol groups (type C) has been introduced for preparation of chemically bonded phases bonded via  $\text{Si}-\text{C}$  instead of  $\text{Si}-\text{O}-\text{C}$  siloxane bonds, providing improved stability at elevated temperatures and low bleed of the

organic-bonded phase. These materials are less polar than the materials with silanol groups and can be used for separation of acids or bases in the normal-phase mode in buffered mobile phases containing ~50–70% organic solvent (acetonitrile).

**Polar-bonded phases** Cyano, diol, and amino bonded phases used in NPLC are generally prepared by chemical modification of the silica gel surface, like the C18 or C8 phases for RPLC. NPLC separations on these columns are usually more convenient and reproducible than on unmodified silica, as they are less sensitive to the control of mobile-phase water content and require shorter equilibration times after the change of the mobile phase. However, silica columns usually have a better stability and a longer lifetime, show better isomer selectivity, higher loadability for preparative separations, and are less expensive. Generally, the strength of the interactions with analytes increases in the order: cyanopropyl < diol < aminopropyl < silica  $\approx$  alumina stationary phases, but selective interactions may change this order. Basic analytes are generally very strongly retained by the silanol groups in silica gel and acidic compounds show increased affinities to aminopropyl columns. Aminopropyl and diol columns prefer compounds with proton-acceptor or proton-donor functional groups (alcohols, esters, ethers, ketones, etc.), while dipolar compounds that cannot have proton-donor or proton-acceptor interactions are usually more strongly retained on cyanopropyl than on aminopropyl silica. Chemically bonded phases with other functionalities such as polyethylene glycol, pentafluorobenzene, or alkyls with embedded amide or carbamate groups are generally intended for reversed-phase applications in water-rich mobile phases. However, at high percentage of organic solvent(s) in the mobile phases, the retention of many compounds increases with increasing concentration of acetonitrile or methanol, showing a typical normal-phase behavior.

**Alumina** Several types of porous alumina are available with pore diameters from 6 to 15 nm and surface areas of 70–250 m<sup>2</sup> g<sup>-1</sup>. Its surface is less homogeneous than silica and contains both hydroxyl groups and aluminum ions with a function of Lewis acid sites. By conditioning with acids or bases, the pH of the surface can be adjusted between pH 3 and 9 and can exhibit both anion-exchange (at low pH) and cation-exchange (at high pH) properties. Heating at 200°C activates the surface of alumina by dehydration; heating at temperatures higher than 900°C causes irreversible loss of activity. Even though the adsorption properties of alumina are

similar to those of silica, there are some differences in selectivity. Alumina favors interactions with  $\pi$  electrons and often yields excellent separation selectivity for compounds with different numbers or spacing of unsaturated (double) bonds, such as polycyclic aromatic hydrocarbons or some steroids. However, it is much less widely used than silica nowadays, because of catalytic properties of its surface, which may cause decomposition or irreversible adsorption of some samples. It is more difficult to bond stationary phases to the surface of alumina than to silica gel, but alumina-based stationary phases are more stable in basic mobile phases.

**Zirconium dioxide** Zirconium dioxide (zirconia) has a polar surface with zirconium atoms as strong Lewis acid sites. Because of empty orbitals, Zr attracts electron-rich Lewis bases such as phosphate anions. Hence, the surface of zirconia has significant cation-exchange properties, giving rise to a mixed-mode retention mechanism. Recently, 3 and 5  $\mu$ m porous and nonporous spherical zirconia particles have become available for HPLC, with 30 nm pore size and 30 m<sup>2</sup> g<sup>-1</sup> specific surface. The primary advantage of zirconia relative to silica is its stability over the entire pH range from 1 to 14 and at temperatures up to 200°C. Like silica, it is mechanically stable and provides high chromatographic efficiency. Stationary phases based on zirconia surface coated with polybutadiene, polystyrene, carbon, or carbon covalently modified with octadecyl groups are intended mainly for RPLC applications. Even though unmodified zirconia is a much weaker adsorbent than silica in nonaqueous solvents, its NPLC applications in the analysis of steroids and plant genins were reported.

### Mobile Phase in Normal-Phase Chromatography

The polarity and the elution strength, i.e., the ability to enhance the elution, generally increases in the following order of most common normal-phase chromatography solvents: hexane  $\approx$  heptane  $\approx$  octane < methylene chloride < methyl-*t*-butyl ether < ethyl acetate < dioxane < acetonitrile  $\approx$  tetrahydrofuran < 1- or 2-propanol < methanol. Large changes in selectivity of normal-phase chromatographic separations can be achieved by selecting the solvent with appropriate type of polar interactions. For chromatography on silica gel, normal-phase chromatographic solvents can be classified as nonlocalizing (e.g., alkanes, aromatic hydrocarbons, chloroalkanes), basic-localizing (e.g., amines and ethers), and nonbasic-localizing (e.g., esters, nitriles, or nitro compounds). Localizing solvents are strongly attracted to adsorption sites,

while nonlocalizing solvents are more or less regularly distributed on the whole adsorbent surface. The basicity of a solvent is understood as its ability of hydrogen-acceptor interactions with the silanol groups.

The selection of the polar solvent **B** strongly affects the separation selectivity in NPLC. A change from a nonlocalizing to a localizing solvent causes large changes in mobile-phase selectivity. Significant differences in selectivity occur also between basic and nonbasic localizing solvents. Changing the type of the solvent **B** may even cause a reversal in the order of elution of sample compounds. **Table 1** lists characteristic properties of some useful solvents for NPLC mobile phases.

**Binary mobile phases** A single solvent only rarely provides suitable separation selectivity and retention in normal-phase systems, which should be adjusted by selecting appropriate composition of a two- or multicomponent mobile phase. Most often, a binary mobile phase is used, containing a weak solvent **A**, usually an alkane, and a more polar organic solvent, **B**, whose concentration controls the elution strength of a mixed mobile phase. Change in retention is a regular function of the concentration of **B** in the mobile phase. As a rule, a twofold increase in percentage of **B** will cause a two- to threefold decrease in the retention factors, *k*, depending on the polarity of the strong solvent **B**. The dependence of the retention in NPLC on the composition of the mobile

<sup>a</sup> Solvent polarity parameters derived from Rohrschneider data.

<sup>b</sup> Solvent strength parameter for NPLC on alumina.

phase can be characterized more exactly on the basis of the simple adsorption model described by eqn [1]. With some simplification, the dependence of the retention factor,  $k$ , on the concentration (volume fraction) of the stronger (more polar) solvent,  $\varphi$ , in binary mobile phases comprising two solvents of different polarities can be described by eqn [2]:

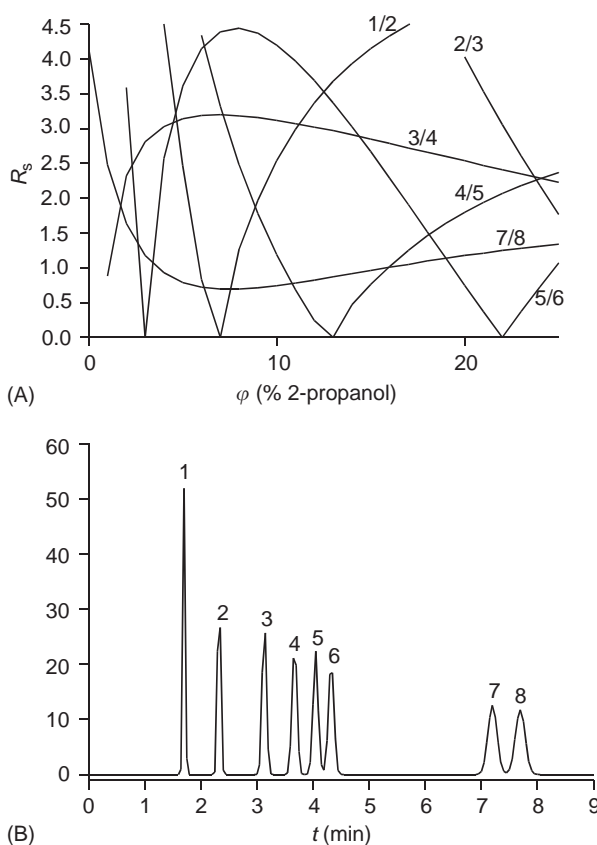

$$k = k_0 \varphi^{-m} \quad [2]$$

Here,  $k_0$  and  $m$  are experimental constants, which depend on the nature of the solute and on the chromatographic system, but are independent of the concentration of the strong solvent,  $\varphi$ , in the mobile phase.  $k_0$  is the retention factor in pure strong (polar) solvent, B. The parameter  $m$  is a measure of stoichiometric exchange in the displacement model of adsorption, i.e., the number of molecules of the strong solvent B necessary to displace one adsorbed sample molecule. Equation [2] applies only for samples strongly retained in the pure nonpolar solvent, A. If the analytes are less strongly retained in pure solvent A, a three-parameter equation [3] can often describe the effect of changing the mobile phase composition on the retention:

$$k = (b + a\varphi)^{-m} \quad [3]$$

The constants  $a$ ,  $b$ , and  $m$  in eqn [3] depend on the solute and on the chromatographic system.  $b = (k_a)^{-m}$ , where  $k_a$  is the retention factor in a pure nonpolar solvent. Equation [2] or [3] can be used as the basis of optimization of the composition of two-component (binary) mobile phases in NPLC, using a common window diagram or overlapping resolution mapping approach, as illustrated in an example in Figure 3.

**Complex mobile phases** Complex mobile phases containing two or more different polar solvents in a nonpolar one can be used to enhance the selectivity in NPLC. Fine tuning of NPLC separations can be based on the 'selectivity triangle' approach, selecting the optimum composition of four-component mobile phases with hexane or heptane as a nonpolar solvent, dichloromethane as a nonlocalizing solvent, methyl *tert*-butyl ether as a basic localizing solvent, and acetonitrile or ethyl acetate as a nonbasic localizing solvent. The concentration of the nonpolar solvent (a diluter) controls the solvent strength and the concentration ratios of the three polar solvents adjust the selectivity for various sample components. To describe the retention in ternary and more complex mixtures, it is principally possible to use the theoretical model of adsorption chromatography, with elution strength contributed to by all solvents in the

**Figure 3** Resolution diagram for the isocratic separation of eight herbicides on a Silasorb SPH silica gel column, 7.5  $\mu\text{m}$ , 300  $\times$  4.2 mm ID as a function of the concentration,  $\varphi$ , of 2-propanol in heptane as the mobile phase (A) and the separation under optimized conditions yielding best resolution of the pairs of compounds 5/6 and 7/8 determined from the window diagram A as 19% 2-propanol (B). Solutes: neburon (1); chlorobromuron (2); 3-chloro-4-methylphenylurea (3); desphenuron (4); isoproturon (5); diuron (6); methoxuron (7); deschloromethoxuron (8). mobile phase, but it would be necessary to consider the competition between various solvents in the mobile phase for localized adsorption centers on the adsorbent surface and to correct correspondingly the solvent strength, which is not straightforward in practice.

**Uptake of water and polar solvents by the column** From mixed mobile phases, polar solvent(s) are preferentially adsorbed on the surface of polar adsorbents, sometimes giving rise to multilayer solvent adsorption on the adsorbent support. In such a case, the retention is contributed to by a liquid–liquid partition mechanism between the adsorbed liquid layer and the bulk mobile phase, in addition to the adsorption. Such a mixed-mode mechanism can be intentionally utilized for separation of strongly polar or even ionic compounds.

The uptake of the polar solvents by the column increases with the polarity of both the solvent and the adsorbent and this effect is especially strong with silica or alumina adsorbents and mobile phases containing minor concentrations of water. Because of the ambient humidity, any organic solvent contains a certain quantity of water if it is in contact with the surrounding atmosphere. This dissolved water is extracted from the mobile phase by the column. As the water content of the column increases, the activity of the adsorbent decreases (eqn [1]), and sample retention times can be greatly reduced compared to a dry column. Ambient humidity seldom remains constant over a longer period of time and as the equilibration of the column can be a very long process, column water content can vary from run to run. Consequently, the reproducibility of the retention data is impaired and long equilibration times are required when the separation conditions are changed. For reproducible results in NPLC, it is necessary to keep a constant adsorbent activity, which can be accomplished by intentional preequilibration of the mobile phase components with water (in the concentration range of a few parts per million). Unfortunately, using 'isohydric' organic solvents with equilibrium water concentrations is time consuming and not very practical. Using mobile phases containing at least 0.1–0.5% polar organic solvent, such as propanol, which mimics the effects of added water, is much simpler to use and often solves the problem.

The reproducibility in normal-phase chromatography can be significantly improved and the column reequilibration times can be short if the temperature is controlled to  $\pm 0.1^\circ\text{C}$  during the separation and dry mobile phases with nonlocalizing polar solvents being used, such as dichloromethane, dioxane, or *tert*-butyl methyl ether. Dehydrated solvents can be kept dry over activated molecular sieves and filtered just before the use to improve the reproducibility. These measures can result in reproducible retention data over a long period of column use, even when using gradient elution technique.

**Gradient elution** During gradient-elution chromatography in normal-phase systems the concentration of one or more polar solvents in a nonpolar solvent is increased. Mixtures of analytes whose polarities span over a large polarity range (such as samples containing fatty acid esters, sterols, and sugars) can be separated in a single run using the so-called incremental gradient elution (or relay gradient elution) with a series of consecutive linear binary gradient steps employing the final solvent **B** from the previous step as the starting solvent **A** in the next step, e.g., a four-solvent three-step gradient elution

starting from hexane to ethyl acetate, continuing from ethyl acetate to acetonitrile, and finishing from acetonitrile to water. Reequilibration of the column between the consecutive runs in 'incremental gradient elution' is tedious and time consuming, hence a single-step gradient elution technique with two miscible solvents such as hexane and 2-propanol is more practical. However, if the two solvents largely differ in polarities, the strong solvent may be completely removed from the mobile phase by adsorption at the first stage of the gradient run, until the breakthrough of the polar solvent occurs, as illustrated in **Figure 4**. This behavior is similar to the situation in TLC or in dry-column liquid chromatography techniques, where it has been known for a long time as the 'solvent-demixing' effect. The extent of the polar solvent uptake by the column during gradient elution depends on the type of the strong solvent B, on the stationary phase, and on the gradient program. This effect may give rise to irreproducible retention, which was the main reason for a strong bias against using gradient elution in normal-phase chromatography.

The preferential uptake of polar solvents by the column can be largely eliminated when starting the gradients at an initial concentration of the polar solvent higher than 3%. If this is not possible, the effects of the preferential adsorption of the polar solvent on the retention can be predicted by numerical calculation from the parameters of the adsorption isotherm of the polar solvent on the column packing material (usually the Langmuir type).

**Normal-phase separation of hydrophilic and ionic compounds** Normal-phase chromatography can sometimes provide satisfactory resolution of hydrophilic and even ionic samples. Very hydrophilic

**Figure 4** Breakthrough curve of 2-propanol in heptane on a Separon SGX silica gel column in normal-phase gradient-elution HPLC calculated using the experimental isotherm data. Gradient 0–50% 2-propanol in 30 min,  $1 \text{ ml min}^{-1}$ .  $V$  – milliliters of eluate from the start of gradient elution,  $\phi$  – concentration of 2-propanol at the outlet from the column. samples such as carbohydrates may be too weakly retained in RPLC systems to allow their separation. They are well retained in normal-phase systems, but usually are not sufficiently soluble in the nonaqueous mobile phases. This problem can be solved by using bonded amine or special stationary phases, such as polyhydroxyethyl aspartamide with aqueous–organic mobile phases in the so-called hydrophilic interaction (HILIC) chromatography. The separation of polar compounds on polar stationary phases in mobile phases containing water is based rather on liquid–liquid partition than on adsorption, but shows characteristic normal-phase behavior – the retention increases in mobile phases with higher concentrations of the organic solvent (acetonitrile, less polar than water) and is higher for more polar samples. Gradients with decreasing concentrations of organic solvents or increasing concentrations of salts (often volatile ones) were successfully applied for the separation of various biological samples. The separation of ionic samples in the HILIC mode can be improved by using weak acids or bases as the mobile phase additives, such as triethylamine for basic compounds and acetic or formic acid for acidic compounds. Good separations of sugars, oligosaccharides, amino acids, or peptides can be achieved by HILIC. **Figure 5A** shows an example of separation of ethoxylated surfactants on an aminopropylsilica

column using an acetonitrile–dichloromethane–water mobile phase. An example of a HILIC separation of sulfonated anionic surfactants in a mobile phase with an ion-pairing reagent is shown in **Figure 5B**.

The ion-exchange capacity of silica and alumina can be used for its dynamic modification by interactions with ions in the mobile phases consisting of an aqueous buffer mixed with an organic solvent. These systems can be used for separations of basic drugs and other weakly basic compounds. Here, the retention mechanism is complex and involves ion-exchange interactions. Organic acids can be separated using normal-phase ion-pairing chromatography with nonaqueous mobile phases, such as organic solutions of tetraalkylammonium hydroxide, which becomes adsorbed on the silica surface. In aqueous–organic mobile phases containing cetyl triethylammonium bromide, the ion pairing reagent is adsorbed in such a way on the silica gel surface that the hexadecyl groups point away from the surface, forming thus an apolar layer similar to chemically bonded alkylsiloxane phases, except that the adsorbed layer is in dynamical equilibrium with the alkylammonium ions in the mobile phase. Anionic solutes are retained as ion pairs and their separation is more reproducible than in ion-pair chromatography on nonpolar chemically bonded phases. However, a relatively long time is required to reach equilibrium compared to

**Figure 5** HILIC separation of the oligomers in a Serdiox NNP4 sample of ethoxylated nonionic surfactants on a Separon SGX Amine column, 7  $\mu\text{m}$ , 150  $\times$  3.3 mm ID, with acetonitrile–water–dichloromethane 49:1:50, mobile phase (A) and of a partially sulfated Serdiox NNP4 sample with acetonitrile–water–dichloromethane 68.6:1.4:30 mobile phase containing 0.04 mol l<sup>-1</sup> cetyl trimethylammonium bromide (B). reversed-phase separations on chemically bonded phases, so that the method development and optimization may be lengthy.

## Applications of Normal-Phase HPLC

NPLC is most suitable for separation of nonionic and moderately polar compounds, especially for lipophilic samples that are too strongly retained by RPLC. Lipids differing in the number and position of double bonds, tocopherol, carotenoids, fat-soluble vitamins, and steroids in pharmaceuticals can be successfully separated by NPLC on silica gel or alumina columns. Mixed lipid classes in the extracts of animal or plant tissues can be analyzed on silica columns or on columns with bonded polyvinyl alcohol using complex solvent gradients. Gradient-elution

NPLC methods were reported for the analysis of natural phospholipids in nervous tissues, meat, etc. Mono-, di-, and triacylglycerol classes in natural oils can be distinguished on silica gel columns using normal-phase gradient elution. In these applications, either low-wavelength UV detection at 205 nm, or evaporative light-scattering detection is used for quantitative analysis.

Normal-phase HPLC usually offers much improved separation of positional isomers or stereoisomers with respect to RPLC. This is also the reason why normal-phase liquid chromatographic mode with nonaqueous mobile phases is often used for the separation of enantiomers on chiral bonded stationary phases.

NPLC is often the method of choice for separation of water-insoluble synthetic polymers and oligomers with polar repeat monomer units or with polar end groups by the so-called interactive liquid chromatography, which usually offers much better resolution than size-exclusion chromatography for lower polymers with molar masses up to 10 000–20 000. Because the effect of increasing concentration of the polar solvent **B** is more significant for polymers than for small molecules (larger values of the parameter *m* in eqn [2] or [3]), successful separation over a broad range of molar masses requires gradient elution, as demonstrated by imperfect isocratic separation of a polystyrene sample with mean molar mass 2350 (Figure 6).

Normal-phase chromatography may provide rapid analyses of samples whose pretreatment involves extraction into a nonpolar solvent, as such samples can be injected directly onto the column, whereas they require evaporation and reextraction into a polar solvent before reversed-phase separation. Figure 7

**Figure 6** Separation of a polystyrene sample with mean molar mass 2350 Da, on two Nova Pak silica gel columns in series, 4  $\mu\text{m}$ , 150  $\times$  3.9 mm ID, in dioxane–hexane 5:95 at 1 ml min<sup>-1</sup>. Detection UV, 254 nm. Halama M and Jandera P, unpublished results.

**Figure 7** Separation of dioctyl phthalate (DOP) and dioctyl adipate (DOA) plasticizers in exhaust gases from an industrial plant. Separon SGX silica gel column, 5  $\mu\text{m}$ , 150  $\times$  3 mm ID; mobile phase: 0.3% 2-propanol in *n*-hexane (v/v), 1 ml min<sup>-1</sup>; temperature: 40°C. Sample volume: 20  $\mu\text{l}$ , UV detection at 230 nm.

shows an example of separation of plasticizers as pollutants in the work place atmosphere, after trapping on a cartridge containing a 60  $\mu\text{m}$  particle C18 sorbent. Hexane should be used for efficient extraction and the extract can be injected directly onto a silica gel column, providing complete separation of dioctyl adipate from dioctyl phthalate, whereas their reversed-phase separation is difficult and the sample requires reextraction into methanol before the HPLC analysis.

### Introduction

Liquid chromatography (LC) was first developed around the turn of the twentieth century and is defined by the International Union of Pure and Applied Chemistry (IUPAC) as a means of physically separating components in mixtures by distributing the components between two phases. One of these phases is moving and percolates through the second, which is stationary. In LC the moving phase or mobile phase is a liquid. The technique has since grown enormously to include the areas of capillary LC, microbore LC, high performance LC (HPLC), and preparative LC. In the following discussion we shall detail the process of solute retention in the technique referred to as reversed-phase liquid chromatography. This is the most widely employed form of liquid chromatography, and in 1997, more than 80% of all HPLC separations were reportedly reversed phase. In this mode of chromatography the stationary phase is a non-polar adsorbent, while the mobile phase is more polar than the stationary phase.

### Reversed-Phase Liquid Chromatography

The first reported use of reversed-phase style LC came in 1948 where Boldingh used a rubber powder stationary phase and an acetone and methanol mobile phase to separate fatty acids. The term reversed phase was subsequently coined by Howard and Martin in 1950 with the separation of fatty acids on a paraffin/*n*-octane stationary phase using aqueous eluents. Because the technique used methods that were opposite to those normally employed, the technique bore the name reversed phase, distinguishing it from the normal-phase separation approach.

The popularity of reversed-phase LC has since escalated, largely because the technique is suitable for the separation of a large number of compounds with varying degrees of polarity and structure. There is a wide range of stationary phase surfaces that support reversed-phase applications and the technique is generally easy to use with fast solvent/stationary phase equilibration times. Typically mobile phases consist of a binary mixture of water plus an organic modifier of methanol, acetonitrile, or tetrahydrofuran. The most common method for preparing nonpolar stationary phases has been through the chemical modification of silica support materials, even though the use of silica-based supports is limited to pHs between 2 and 7 (although some silica-based supports have been prepared that

### Introduction

Liquid chromatography (LC) was first developed around the turn of the twentieth century and is defined by the International Union of Pure and Applied Chemistry (IUPAC) as a means of physically separating components in mixtures by distributing the components between two phases. One of these phases is moving and percolates through the second, which is stationary. In LC the moving phase or mobile phase is a liquid. The technique has since grown enormously to include the areas of capillary LC, microbore LC, high performance LC (HPLC), and preparative LC. In the following discussion we shall detail the process of solute retention in the technique referred to as reversed-phase liquid chromatography. This is the most widely employed form of liquid chromatography, and in 1997, more than 80% of all HPLC separations were reportedly reversed phase. In this mode of chromatography the stationary phase is a non-polar adsorbent, while the mobile phase is more polar than the stationary phase.

### Reversed-Phase Liquid Chromatography

The first reported use of reversed-phase style LC came in 1948 where Boldingh used a rubber powder stationary phase and an acetone and methanol mobile phase to separate fatty acids. The term reversed phase was subsequently coined by Howard and Martin in 1950 with the separation of fatty acids on a paraffin/*n*-octane stationary phase using aqueous eluents. Because the technique used methods that were opposite to those normally employed, the technique bore the name reversed phase, distinguishing it from the normal-phase separation approach.

The popularity of reversed-phase LC has since escalated, largely because the technique is suitable for the separation of a large number of compounds with varying degrees of polarity and structure. There is a wide range of stationary phase surfaces that support reversed-phase applications and the technique is generally easy to use with fast solvent/stationary phase equilibration times. Typically mobile phases consist of a binary mixture of water plus an organic modifier of methanol, acetonitrile, or tetrahydrofuran. The most common method for preparing nonpolar stationary phases has been through the chemical modification of silica support materials, even though the use of silica-based supports is limited to pHs between 2 and 7 (although some silica-based supports have been prepared that

are stable to pH 9). The surface modification of silica has largely been based on organosilanization, according to a generalized reaction scheme shown below:

where X is a reactive group, such as a halide (usually chloride),  $R'$  is typically a methyl or ethyl group, and R is the main group that imparts a hydrophobic (nonpolar) nature to the stationary phase surface (for instance an octyldecyl (C18) chain). When the surface modification takes place to yield a monomeric surface coverage, the reactive group on the organosilane reacts with hydroxyl groups located on the silica surface, at a concentration that usually does not exceed  $4 \mu\text{mol m}^{-2}$ . Such a surface coverage usually results in approximately only half the silica hydroxyl groups undergoing reaction, even less for lower surface coverages. These residual hydroxyl groups can lead to detrimental chromatographic performance, particularly in the analysis of basic solutes, hence it is important to protect the solute interactions from these hydroxyl groups. This can be achieved in a number of ways; through a process referred to as endcapping, the employment of polymeric surface coverages, or by using silanizing reagents that have  $R'$  groups that are longer and more hydrophobic than methyl groups in combination with endcapping. When endcapping is employed, a reversed-phase moiety such as trimethyl silane is reacted with the residual hydroxyl groups in the same process as for the coating of the particles with the reversed-phase ligand. The endcapping reagent has a smaller hydrodynamic volume than the main reversed-phase ligand and is able to access a higher proportion of the unreacted hydroxyl groups that underlie the main surface coverage. Protection of solutes from residual hydroxyl groups can be achieved by coating the particles with a polymeric surface coverage. A polymeric surface coverage is produced when organosilanes with multiple reactive X groups (i.e., trichloro-organosilanes) are used instead of organosilanes that have a single reactive X group (i.e., chloro-organosilanes), in which case a monomeric surface coverage is produced. This effectively results in a cross-linking process that protects the surface. However, polymeric coatings have been attributed to a decrease in the performance of the chromatographic system due to increases in mass transfer into the stationary phase layer. The third

approach to protect solutes from interactions with residual hydroxyl groups in which organosilanes that have longer and more hydrophobic  $R'$  groups (i.e., hexyl) than the methyl  $R'$  counterparts, in conjunction with endcapping, results in a surface whereby the extended  $R'$  groups are purportedly capable of providing a hydrophobic surface environment in close proximity to the silica surface.

Examples of reversed-phase HPLC bonded phases are given in Table 1. These include: alkyl bonded silica, where the R group is an alkyl chain, the length of which determines the degree of hydrophobicity (C18, C8, C4, etc.); the phenyl stationary phase,

**Table 1** List of some commonly used reversed-phase bonded stationary phases

Type of reversed-phase stationary phase	Structure
Octadecyl (ODS) C18	$\begin{array}{c} R' \\   \\ \text{Si—O—Si—} \text{CCCCCCCCCCCCCCCCCC} \\   \\ R' \end{array}$
Octyl C8	$\begin{array}{c} R' \\   \\ \text{Si—O—Si—} \text{CCCCCCCC} \\   \\ R' \end{array}$
Phenyl	$\begin{array}{c} R' \\   \\ \text{Si—O—Si—} \text{C}_6\text{H}_5 \\   \\ R' \end{array}$
Propyl phenyl	$\begin{array}{c} R' \\   \\ \text{Si—O—Si—} \text{CH}_2\text{CH}_2\text{C}_6\text{H}_5 \\   \\ R' \end{array}$
Hexyl phenyl	$\begin{array}{c} R' \\   \\ \text{Si—O—Si—} \text{CCCCC—C}_6\text{H}_5 \\   \\ R' \end{array}$
Amino ( $\text{NH}_2$ )	$\begin{array}{c} R' \\   \\ \text{Si—O—Si—} \text{CH}_2\text{CH}_2\text{NH}_2 \\   \\ R' \end{array}$
Nitrile (cyano – CN)	$\begin{array}{c} R' \\   \\ \text{Si—O—Si—} \text{CH}_2\text{CH}_2\text{C}\equiv\text{N} \\   \\ R' \end{array}$

which may offer a change in the selectivity due to the possibility of  $\pi$ - $\pi$  interactions; cyano (nitrile) and amino surfaces, which can be employed in both reversed- and normal-phase mode since they possess a medium polarity. More recently, new 'polar end-capped' reversed-phase stationary phases have been developed, although applications based on the use of these materials are presently limited. The exact nature of the 'polar' endcapping agents is currently proprietary and little has been reported on the mechanisms of retention. However, the general consensus with regard to the mode of operation is that the polar endcapping agents repel basic species from within the region near the support surface. By far the most popular reversed-phase material is the C18 stationary phase and a multitude of applications using C18 columns are reported in the literature.

Other stationary phase supports that are employed for reversed-phase separations include a variety of polymeric resins (such as polystyrene-divinylbenzene). These types of stationary phases were originally developed in an effort to overcome the problems associated with residual hydroxyl groups on the surface of silica and also allow for separations to be performed in alkaline solvents. Polymeric resins are generally less well received than silica-based supports because initial manufacture produced columns that suffered from problems associated with swelling in changing solvent environments. This affected the pore structure and the pressure within the column. The modern polymeric column is, however, far more robust than its predecessor and in many respects chromatographers who may have initially employed polymeric resins in their early days may find new joy in the modern polymeric stationary phase. The use of polymeric columns finds a niche in HPLC/MS/MS, mainly as a consequence of the pH stability of the polymeric resins. This allows these columns to be employed in either very basic or acidic solvents, which are often required in chemical ionization procedures. Another advantage of the polymeric resins is that the surface is homogeneous, resulting in a decreased likelihood of secondary elution mechanisms through interactions with residual hydroxyl groups. However, the homogeneity of the surface may also be a disadvantage as it somewhat limits the selectivity of the surface.

Porous graphitic carbon has also been used as a nonbonded reversed-phase surface. This has a rigid structure, is chemically stable, hydrophobic, and displays different selectivity compared to silica-based stationary phases. Porous graphitic carbon is composed of sheets of hexagonally arranged carbon atoms showing  $sp^2$  hybridization and has a regular, homogeneous, and flat surface. These types of

surfaces are particularly useful for the separation of isomeric mixtures, such as geometric and diastereomers and in the analysis of highly polar analytes normally not retained on C18-silica. A number of review articles have been published on porous graphitic carbon. One particular advantage of porous graphitic carbon is that it is stable at high temperatures, and across the pH range 1–14 and is resistant to organic solvents. In addition to graphitic carbon surfaces, carbon clad zirconia is a second type of carbonaceous reversed-phase surface. The carbon clad zirconia stationary phase is a relatively new surface in which zirconia microspheres are coated with a light hydrocarbon (rather than the conventional silica support). The hydrocarbon is then pyrolyzed onto the zirconia surface, resulting in a superficial carbonaceous surface in many ways resembling a pure carbon support. However, the carbon clad zirconia support is more rigid and has a more easily controlled pore structure than its porous graphitic carbon counterpart. Carbon-clad zirconia supports are hydrophobic in nature and retain solutes based on electronic ( $\pi$ - $\pi$ ) interactions. They are often selective in the separation of isomers, particularly stereoisomers. Both the carbon-clad zirconia and porous graphitic carbon supports offer unique retention mechanisms selective for isomer separations. While these surfaces do behave as a reversed-phase adsorbent, they possess many unique chromatographic characteristics and therefore translations between chromatographic methods from conventional supports may be difficult. An interesting illustration as to the differences in retention processes that are apparent for various carbon surfaces, such as carbon-clad zirconia in comparison to bonded phase surfaces, such as C18-silica can be found in the elution behavior of oligostyrenes. The chromatograms illustrated in **Figure 1** show this effect for an oligostyrene with four configurational repeating units and a *sec*-butyl end group. For such an oligomer there are eight diastereomers, four of which result from the variation in tacticity associated with the stereochemistry of the main chain, while the remaining four diastereomers result from the stereochemical site in the *sec*-butyl end group. On a C18 column using an acetonitrile mobile phase, the oligostyrenes elute with some diastereomer selectivity (**Figure 1A**). However, when a carbon-clad zirconia column is employed, the diastereomer selectivity is highly expressed and seven diastereomers are apparent (**Figure 1B**). Of significance is the fact that a C18 column was 250 mm in length, packed with 5  $\mu$ m particles compared to the carbon-clad zirconia column, which was 100 mm in length, packed with 3  $\mu$ m particles.

**Figure 1** Illustration of the isomeric separation of oligostyrene containing four configurational repeating with a *sec*-butyl end group on (A) a C18 column (250 mm × 4.6 mm, Pd 5 μm) and (B) a carbon clad zirconia column (100 mm × 4.6 mm, Pd 3 μm). Both separations were in a mobile phase of 100% acetonitrile at 30°C.

## Retention in Reversed-Phase Liquid Chromatography

While virtually any compound, including, for example, amino acids, peptides, and proteins, may potentially be separated in a reversed-phase mode, the technique is ideally suited to the separation of hydrocarbons, substituted aromatics, homologs, and polymers. Generally, reversed- and normal-phase methods of separation are considered to be restricted to molecules with molecular weights less than 5000 Da; however, there are many reports in the literature on the reversed-phase separation of polymers with molecular weights up to one million Daltons.

Despite reversed phase chromatography being more than 50 years mature, there still exists considerable debate regarding the retention processes involved. Much of this debate has discussed processes of adsorption versus those of partitioning. Here the basic difference between these models lies in the solute association with the stationary phase. In partitioning, the solute is embedded within the stationary phase, as distinct from adsorption where the solute is

in contact with the stationary phase, but not fully embedded as is the case with partitioning. In partitioning, there are three distinct processes that occur: (1) the creation of a solute sized cavity within the stationary phase; (2) the transfer of the solute from the mobile phase into the cavity created within the stationary phase; and (3) the closure of the solute-sized cavity in the mobile phase that was vacated by the solute upon transfer to the stationary phase. A lattice model theory was used to describe this process taking into account the relevant contact interactions between solute molecules and those of the stationary and mobile phases. This process is driven by the relative chemical affinities between the solute and stationary and mobile phase molecules. These interactions may be considered as being coulombic, if for instance, the interacting molecules possess a net charge, or they may be dipole-dipole interactions if the interacting molecules contain temporary dipole moments. These types of interactions may also be governed by specific molecular orientation associated with the alignment of molecules undergoing, say, hydrogen bonding. The associated enthalpic and entropic contributions need then be considered in the retention process. The lattice model theory also describes the process of adsorption. However, the driving force for adsorption is much weaker than that of partitioning because the contact surface area of the solute contained on the surface of the stationary phase is lower than that of the solute when embedded within the stationary phase. The process for adsorption differs from partitioning in regards to the creation of a cavity adjacent to the stationary phase, rather than within the stationary phase.

In reality, retention need not be governed solely by either adsorption or partitioning. A combination of these retention processes may result, depending upon the nature of the solute molecule and the stationary phase environment. Because stationary phases are fixed to a support material, they do not behave as a bulk liquid. Instead the bonded moiety contains a degree of order that increases as the surface density increases. Solute partitioning then becomes entropically unfavourable within the increasing ordered system, especially since the inclusion of a solute molecule into the stationary phase further increases the state of order within the system. Hence adsorption processes dominate on higher density stationary phases, or when the size of the solute increases to the point whereby it is in effect excluded from within the bulk phase. Plots of  $\log k$  versus the carbon number of a homologous series undergoing chromatographic retention on alkyl chain (C18, C8, and C4 for example) modified silica illustrate this affect clearly.  $\log k$  increases linearly with respect to the number of

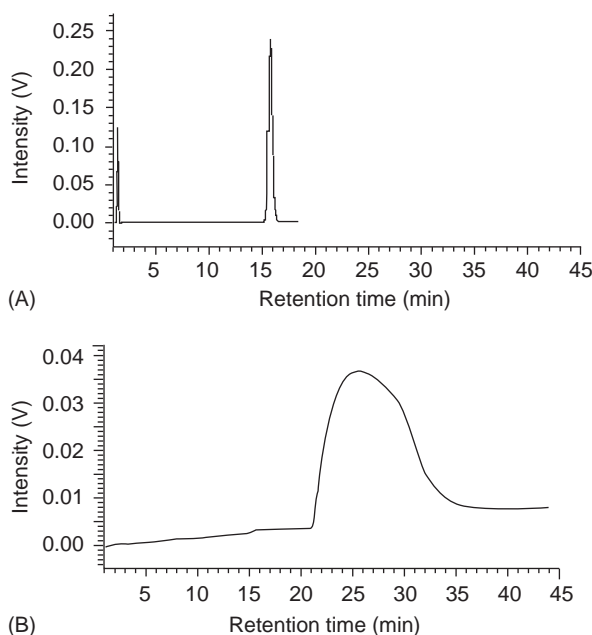

carbon atoms of the homolog, until the carbon number of the solute approximately equals the length of the organic ligand of the stationary phase. This discontinuity indicates a change in retention mechanism from that of pure partitioning to a mixed process of partitioning and adsorption, after which steric factors prevent solute molecules undergoing partitioning, and adsorption consequently dominates. Adsorption also dominates on stationary phases prepared from short chain ligands, such as the C4, as these ligands are highly restricted in their degree of freedom.

Partitioning and adsorptive type retention mechanisms only explain in part the nature of solute interactions with the stationary phase. The separation of isomers, for example, must be explained by the shape selectivity of the reversed-phase surface. Stationary phase ligands bonded to the support surface are able to exist in a considerable number of molecular orientations. The molecular shape of solute molecules and their orientation with respect to the stationary phase ligands determines their degree of retention. The relative change in free energy is more substantial for a solute molecule that aligns parallel to the stationary phase surface, rather than normal, hence the shape selectivity of the surface. Studies using isomeric polyaromatic hydrocarbons have illustrated this effect. Retention has been shown to increase according to rods > disks > flexible chains.

Any discussion regarding reversed-phase LC would be incomplete without comment regarding the solvophobic theory. This theory was essentially the first attempt to fully describe the retention process in reversed-phase liquid chromatography. The solvophobic theory predicts that the stationary phase plays a passive role and retention is largely governed by the exclusion of the solute from the mobile-phase environment. In this theory, the mobile-phase molecules are considered to exist in an extensive network of hydrogen bonding due to the hydro-organic nature of the mobile phase. The water molecules more favourably prefer to bond with each other rather than interact with solute molecules. Consequently, nonpolar solute molecules distributed within the aqueous mobile phase are believed to exist in a highly ordered network. Thus, it is entropically unfavourable to put a nonpolar molecule within the aqueous mobile phase. Consequently, exclusion of this nonpolar molecule from the aqueous phase and its subsequent association with the nonpolar reversed-phase ligand is said to be entropically favourable as the ordered mobile phase attains a disordered configuration following expulsion of the solute. The expulsion of the solute from the mobile phase is thought to be the driving force for retention. The solvophobic

theory, however, offers an incomplete description of the retention process. The independence of solute retention on the type of stationary phase is not supported by the ample experimental evidence that shows retention being determined by the nature of the stationary phase, as well as the nature of the mobile phase.

Whether the mechanism of retention is dominated one way or the other by partitioning or adsorption may in many respects be considered immaterial to the separation process. What is important, however, is attaining resolution. For this part correct selection of the stationary phase and mobile phase combinations is paramount. Factors that lead to loss in resolution include (the obvious) lack of selectivity and (the not so obvious) secondary elution processes that lead to band distortions often revealing themselves in band tailing. An example of poor column selection may be found in the analysis of polyaromatic hydrocarbons. On an alkyl-bonded column (C18) band shape is uniform (Figure 2A), but on a carbon-clad zirconia column significant peak tailing is observed (Figure 2B). This effect is also apparent, but to a lesser extent on phenyl columns. For these types of solutes, as the  $\pi$ - $\pi$  interactions become more significant, band tailing increases and the separation performance decreases. Incidentally, the difference in retention behavior of these solutes on the different stationary phases is also an indicator that the role played by the stationary phase is more

**Figure 2** Chromatograms of pyrene illustrating the band tailing that is observed on a carbon clad zirconia reversed-phase column in comparison to a C18 reversed-phase column.

substantial than considered in the solvophobic theory.

The development of reversed-phase chromatographic media has intensified during the last decade. Now, many manufacturers pride themselves on their high degree of the batch to batch reproducibility, both with respect to the retention properties of the stationary phase and also in regards to the quality of the packed bed. Recent years have seen the development of a variety of polar embedded and polar endcapped reversed-phase materials. There is in reality no limitation placed on the type of reversed-phase material that could be used for reversed-phase applications, other than commercial availability. Therefore expansion of the available reversed-phase media that enter the market place continues, as chromatographers continually seek new ways to gain selectivity.

## Introduction

Ion pair extraction is a technique used for the distribution of ionic compounds to an organic phase with the aid of counterions of opposite charge. Ion pairs are formed in the organic solvent, e.g., the extraction of a cation  $\text{HA}^+$  with an anion  $\text{X}^-$  making up an ion pair HAX, and the distribution of the ion pairs is dependent on their solvation properties. In organic analysis, this ion pair extraction methodology was originally used to extract basic and acidic compounds with counterions of different hydrophobicity as well as a means to provide selectivity and enable detection for analytes with low inherent detectability. Counterion-aided extraction has been widely applied in liquid–liquid extraction but during the last two decades the main use of the ion pair technique has been in reversed-phase liquid chromatography (LC), an important separation technique for ionic compounds in organic and biomedical analysis.

In chromatography, the ion pair technique was first used in liquid–liquid chromatography where the counterion was supplied through the aqueous phase and the ion pair distributed to the organic phase. In the normal or straight-phase mode, the ionic solutes are transported as ion pairs in the mobile organic

phase; in the reversed-phase mode the solutes are retained as ion pairs in the stationary organic liquid phase. However, due to strong demands on temperature control and liquid–liquid equilibration, liquid–liquid chromatography was early on substituted by liquid–solid chromatography owing to the relative ease of this technique.

In the normal-phase mode ion pair adsorption or liquid–solid chromatography found a couple of applications but since the entry of bonded phases, reversed-phase LC has been a quite dominating separation technique and the main one employing the ion pair concept. Ion pair chromatography has been the most widely used name for this separation method, but terms such as dynamic ion exchange, ion interaction, and paired ion chromatography have also been used, where retention is due to electrostatic, hydrophobic, and polar interactions.

## Principles of Ion Pair Formation

The ion pair formation process in the extraction of two oppositely charged ionic compounds to an organic phase is most often expressed by the equilibrium

where  $\text{HA}^+$  is a protonated amine, a quaternary ammonium ion, or any other cation and  $\text{X}^-$  is an ionized acid or other anions. HAX is the ion pair

substantial than considered in the solvophobic theory.

The development of reversed-phase chromatographic media has intensified during the last decade. Now, many manufacturers pride themselves on their high degree of the batch to batch reproducibility, both with respect to the retention properties of the stationary phase and also in regards to the quality of the packed bed. Recent years have seen the development of a variety of polar embedded and polar endcapped reversed-phase materials. There is in reality no limitation placed on the type of reversed-phase material that could be used for reversed-phase applications, other than commercial availability. Therefore expansion of the available reversed-phase media that enter the market place continues, as chromatographers continually seek new ways to gain selectivity.

## Introduction

Ion pair extraction is a technique used for the distribution of ionic compounds to an organic phase with the aid of counterions of opposite charge. Ion pairs are formed in the organic solvent, e.g., the extraction of a cation  $\text{HA}^+$  with an anion  $\text{X}^-$  making up an ion pair HAX, and the distribution of the ion pairs is dependent on their solvation properties. In organic analysis, this ion pair extraction methodology was originally used to extract basic and acidic compounds with counterions of different hydrophobicity as well as a means to provide selectivity and enable detection for analytes with low inherent detectability. Counterion-aided extraction has been widely applied in liquid–liquid extraction but during the last two decades the main use of the ion pair technique has been in reversed-phase liquid chromatography (LC), an important separation technique for ionic compounds in organic and biomedical analysis.

In chromatography, the ion pair technique was first used in liquid–liquid chromatography where the counterion was supplied through the aqueous phase and the ion pair distributed to the organic phase. In the normal or straight-phase mode, the ionic solutes are transported as ion pairs in the mobile organic

phase; in the reversed-phase mode the solutes are retained as ion pairs in the stationary organic liquid phase. However, due to strong demands on temperature control and liquid–liquid equilibration, liquid–liquid chromatography was early on substituted by liquid–solid chromatography owing to the relative ease of this technique.

In the normal-phase mode ion pair adsorption or liquid–solid chromatography found a couple of applications but since the entry of bonded phases, reversed-phase LC has been a quite dominating separation technique and the main one employing the ion pair concept. Ion pair chromatography has been the most widely used name for this separation method, but terms such as dynamic ion exchange, ion interaction, and paired ion chromatography have also been used, where retention is due to electrostatic, hydrophobic, and polar interactions.

## Principles of Ion Pair Formation

The ion pair formation process in the extraction of two oppositely charged ionic compounds to an organic phase is most often expressed by the equilibrium

where  $\text{HA}^+$  is a protonated amine, a quaternary ammonium ion, or any other cation and  $\text{X}^-$  is an ionized acid or other anions. HAX is the ion pair

formed in the organic phase. The equilibrium constant summarizing the process is defined by

$$K_{\text{ex(HAX)}} = \frac{[\text{HAX}]_{\text{org}}}{[\text{HA}^+]_{\text{aq}}[\text{X}^-]_{\text{aq}}} \quad [2]$$

and expresses the combined effect of phase transfer of the ions and ion pair formation in the organic phase. The magnitude of the extraction constant,  $K_{\text{ex(HAX)}}$ , depends on the hydrophobic properties of the two ions forming the ion pair, the extent of electrostatic and hydrogen-bonding interaction and on the nature of the organic phase.

If processes other than the one given in eqn [2] can be disregarded, the distribution ratio for  $\text{HA}^+$ ,  $D_{\text{HA}}$ , is expressed by the product of the extraction constant and the concentration of the counterion,  $\text{X}^-$ , in the aqueous phase:

$$D_{\text{HA}} = \frac{[\text{HAX}]_{\text{org}}}{[\text{HA}^+]_{\text{aq}}} = K_{\text{ex(HAX)}}[\text{X}^-]_{\text{aq}} \quad [3]$$

For a given organic solvent the extraction constant and the concentration of the counterion will accordingly determine the distribution ratio.

In a normal-phase liquid-liquid chromatographic system with a nonpolar mobile phase, in which the ion pair is migrating, the retention factor (capacity factor) is given by

$$k_{\text{HA}} = q/D_{\text{HA}} = q/K_{\text{ex(HAX)}}[\text{X}^-]_{\text{aq}} \quad [4]$$

where  $q$  is the volume ratio  $V_{\text{stat}}/V_{\text{mob}}$ .

In a corresponding reversed-phase system, where the ion pairs are retained in the stationary organic phase, the expression will be

$$k_{\text{HA}} = qD_{\text{HA}} = qK_{\text{ex(HAX)}}[\text{X}^-]_{\text{aq}} \quad [5]$$

Equations [4] and [5] can be used to calculate the retention factors for a given ion pair system or to choose conditions for suitable retention of the ionic solute. A more hydrophobic counterion  $\text{X}^-$  (higher  $K_{\text{ex(HAX)}}$ ) in higher concentration will increase the distribution of  $\text{HA}^+$  to the organic phase. This will decrease (eqn [4]) or increase (eqn [5]) the retention factor. The accuracy of the predictions made depends on the inertness of the chromatographic packing material used as support for the liquid stationary phase. Deviations between calculated and obtained retention data are often quite large owing to interactions of the solid phase with the ionic compounds.

The ion pair concept as described in eqns [1] and [2] implies transfer of ionic compounds between two liquid phases with maintenance of electroneutrality, ion pairs being formed in the nonpolar organic

phase. The process could be named counterion-aided extraction rather than ion pair extraction, since the latter may indicate that ion pair formation in the aqueous phase is preceding the phase transfer. However, it should be emphasized that this is by no means an inevitable first step, although the mechanism is not fully elucidated. It is reasonable to assume that ion pairs are formed when ionic species are distributed to a nonpolar organic solvent as in liquid-liquid extraction or liquid-liquid chromatography. As regards reversed-phase adsorption chromatography, it is more difficult to imagine ion pair formation in the hydrophobic bonded phase. The role of an adsorbed counterion is to induce a charged surface or, by the adsorption of an ionic solute, to bring about electroneutrality. The following will mainly be devoted to ion pair LC in the reversed-phase mode, which is the technique of most interest.

## Comparison of Theoretical Models

In ion pair separations with a hydrophobic solid stationary phase, most often alkyl-bonded silica, the binding capacity is limited. The principles of retention in such a system can be expressed as follows: (1) the retention of an ionic solute,  $\text{HA}^+$ , is accompanied by the displacement of a system ion of the same charge or by the binding of a counterion,  $\text{X}^-$  and (2) the solute and the components in the mobile phase may compete for the binding capacity of the adsorbing solid phase.

The overall retention of  $\text{HA}^+$  can be expressed in a simplified way assuming a Langmuir adsorption on to a homogeneous solid phase

$$k_{\text{HA}} = \frac{qK^\circ K_{\text{HAX}}[\text{X}^-]_{\text{aq}}}{1 + K_{\text{QX}}[\text{Q}^+]_{\text{aq}}[\text{X}^-]_{\text{aq}}} \quad [6]$$

where  $K^\circ$  is the capacity of the adsorbent,  $K_{\text{HAX}}$  and  $K_{\text{QX}}$  are distribution constants, and  $\text{Q}^+$  and  $\text{X}^-$  are ionic components in the mobile phase. Equation [6] shows that the retention factor of  $\text{HA}^+$  can be influenced by the nature of the counterion,  $\text{X}^-$ , and its concentration. However, an increase of the hydrophobicity and concentration of the counterion will also increase the denominator, giving a curved relationship as demonstrated in **Figure 1**. When unity in the denominator can be disregarded, e.g., with a hydrophobic counterion  $\text{X}^-$  in increasing concentration, eqn [6] will express an ion-exchange process between  $\text{HA}^+$  and  $\text{Q}^+$ .  $\text{Q}^+$  is a cation in the mobile phase such as potassium in a phosphate buffer or sodium with octyl sulfate counterion, and may also be a hydrophobic cation such as dimethyloctylammonium.

**Figure 1** Retention of anionic and cationic compounds with 1-phenethyl-2-picolinium (PEP) in the mobile phase. Stationary phase:  $\mu$ Bondapak Phenyl. Mobile phase: PEP in  $0.1 \text{ mol l}^{-1}$  acetic acid. UV detection at 254 nm. (Reprinted with permission from Denkert M, Hackzell L, Schill G, and Sjögren E (1981) Reversed-phase ion-pair chromatography with UV-absorbing ions in the mobile phase. *Journal of Chromatography* 218: 31–43; © Elsevier.)

The presence in the mobile phase of a competing alkylammonium ion,  $Q^+$ , will decrease the retention of  $HA^+$  as illustrated in **Figure 1**, and may also, in particular for hydrophobic cationic solutes, decrease tailing. The unsatisfactory performance of certain aliphatic ammonium compounds was more pronounced in the past but modern and improved reversed-phase packings have largely eliminated the need for precautions by including an ionic modifier in the mobile phase. The observed effects indicating how the retention is influenced by the concentration and hydrophobicity of a counterion  $X^-$  and competing cation  $Q^+$  are largely in accordance with eqn [6]. However, it must be emphasized that this model does by no means explain the mechanism of 'ion pair' chromatography, neither do alternative stoichiometric models such as 'dynamic ion exchange' and 'ion interaction' chromatography. Ion pair formation in the mobile phase is still in some instances proposed as preceding ion pair adsorption. However, equilibrium constants for ion pair formation in aqueous phases reported in literature are, with a few exceptions, small and this process is not a prerequisite for ion pair extraction to an organic solvent or to adsorption of an ionic solute to an organic solid phase. Neither is it probable that micelle formation in the mobile phase is responsible for unanticipated retention effects unless conditions for micelle formation are at hand.

The retention of a solute in chromatography is determined by thermodynamic equilibria, and non-stoichiometric theories have been developed for qualitative evaluation of ion pair chromatography.

These theories are based on the interaction of the solute ion with the charged surface layer established by the adsorbed counterion and by adsorbed competing ions. The nonstoichiometric models apply the Poisson–Boltzmann equation to estimate retention from an electrostatic point of view. The electrical double-layer model applied uses different approaches such as 'liquid partition', 'surface adsorption, diffuse layer ion-exchange', and 'surface adsorption' double-layer models. It is not possible to draw conclusions about the ion pair process from chromatographic retention data, but each model and theory may find use in describing experimental results under the particular conditions studied.

The variability in hydrophobicity and other properties of the solid phase and in concentration of the ionic species involved will make little sense for elucidations of more general validity. The heterogeneous nature of the adsorbing phase, most often  $C_8$  or  $C_{18}$  bonded silica, contributes to the complexity of the systems. Whatever approach is being used it must be emphasized that ion pairs are not fixed complexes in solution and even less on a surface. They represent a dynamic equilibrium in which the solute ion is transported or retained by the aid of the counterion, and electrostatic, hydrophobic, and other interaction provide overall electroneutrality. In this context it should be made clear that although the treatment so far has dealt with  $HA^+$  as solute ion and  $X^-$  as counterion, the considerations made are as valid for the opposite system with  $X^-$  as ionic solute and  $HA^+$  as counterion in the mobile aqueous phase.

## Range of Anion and Cation Pairing Reagents

There is a wide range of counterions that can be used in reversed-phase ion pair chromatography. Besides the hydrophobicity, the concentration of the counterion will influence retention. Concentrations used in the mobile aqueous phase are often in the region of  $0.001\text{--}0.1\text{ mol l}^{-1}$  depending on the hydrophobicity and solubility of the counterion. If either of the ionic species originates from a weak protolyte, pH has to be controlled by a pH-buffering electrolyte or the protolyte being present along with the counterion. Strong or weak acids may act as both ion pairing and pH buffering agents in the pH region of 2–8, available for most bonded silica packings. As a rule both the solute and the counterion should be in ionic form at the pH chosen. This means that strong protolytes like quaternary ammonium ions and sulfonates are well suited since they are aprotic and can be used irrespective of pH. Some anions and cations are listed in Table 1 to exemplify the counterions that are used. For normal separation the counterion should preferably be invisible to the detector. As can be seen in Table 1, there is a wide difference in physicochemical properties among the counterions listed. The choice of counterion should, of course, be adapted to the hydrophobic properties of the ionic solute. Lately, the evolving dominant position of mass spectrometry (MS) as detection mode in LC has put strong demands also on volatility of the ion pairing agent and the pH buffering electrolyte.

### Retention

Dihydrogenphosphate as a pH-buffering ion may give appropriate retention and separation of hydrophobic ammonium compound such as tricyclic

alkylamines. Hydrophilic catecholamines require a counterion like octyl sulfate or dodecyl sulfate (lauryl sulfate) to achieve sufficient retention. Perfluorinated carboxylic acids have found increased use in LC–MS applications due to their volatility; not only trifluoroacetate and heptafluorobutyrate but also higher perfluorinated carboxylic acids have been used.

Strongly lipophilic anionic solutes such as arylalkanesulfonates may not need a separate counterion beside sodium or potassium to be added for sufficient retention. Tetrabutylammonium has been used for moderately hydrophilic anionic solutes and cetyltrimethylammonium (cetrimide) for strongly hydrophilic ones. In recent reports, a couple of amines, such as triethylamine and dimethylhexylamine, have been introduced as cationic agents in LC–MS applications.

For a given solute there are in most instances alternative ionic systems, e.g., a more hydrophobic counterion in low concentration or a less hydrophobic ion in higher concentration, which may give similar retention. For major adjustment of the retention in an ion pair system, a different counterion should be selected that is either more hydrophobic or more hydrophilic depending on whether the solute is eluting too fast or too slowly. If only minor changes in retention are required, the counterion concentration in the mobile phase can be increased or decreased.

The discussion so far has not concerned the presence of an organic solvent in the aqueous mobile phase as a modifier. This is as obvious here as in other forms of reversed-phase LC. The same kind of organic modifiers are used, such as acetonitrile, methanol, 2-propanol, and tetrahydrofuran. Increased contents of these solvents will give decreased retention of the solutes, and their concentration can be used to regulate the eluent strength. In ion pair reversed-phase chromatography, minor changes in the retention of the solute are preferably made in this way. The organic modifier is, along with the nature and concentration of the counterion, decisive for the retention of the solute. Different combinations of the variables may give retention factors of the same magnitude. A hydrophobic counterion and a high content of organic solvent may give the same retention as a more hydrophilic counterion combined with a low degree of organic modifier.

Different combinations of phase systems may provide the gain in selectivity needed for difficult separations between ionic solutes of the same charge. The selectivity effects are even more pronounced for the resolution of two interfering sample components that are retained by different principles, e.g., one uncharged solute and one subjected to ionic interaction. For the selectivity of ion pair liquid

Cetyltrimethylammonium

chromatographic systems, the same rules or lack of rules apply as for other kinds of reversed-phase chromatography. Specific interactions, besides electrostatic, between the counterion and the ionic solute cannot be excluded but is by no means as obvious as in liquid-liquid distribution systems. Small selectivity changes that are often sufficient to separate two co-eluting components may be induced by using another organic modifier or by testing different combinations of counterion and content of organic solvent in the aqueous mobile phase. However, by the introduction of MS detection the issue of selectivity in LC separations has become less demanding than with other detection principles.

Ion pairing agents in liquid-liquid systems in reversed-phase mode have included dihydrogenphosphate for separation of tricyclic amines, octyl sulfate for catecholamines, and tetrabutylammonium for aromatic carboxylates and anions of sulfonamides, to exemplify some of the comparatively few applications. Liquid stationary phases coated on the alkyl-bonded phase include 1-pentanol, butyronitrile, and tributylphosphate. In normal-phase liquid-liquid ion pair chromatography aqueous perchlorate solution has been coated on to silica particles for ion pair separation of catecholamines and related compounds and tetrabutylammonium ion at neutral pH for carboxylates and anions of sulfonamides. The organic mobile phase often contained dichloromethane and butanol. In the normal-phase mode on silica alternative separation systems have been described with aqueous perchloric acid in methanol added to dichloromethane as mobile phase for separation of amines such as drug substances. This is not an extensively utilized, but quite useful, kind of separation, which has been named ion pair adsorption chromatography.

### Detection

In most instances it is preferable that the ion pairing reagent is invisible for the detection principle used and gives no background. The ionic agents discussed here have this property, being either alkyl sulfates or alkanesulfonates, or ammonium ions or inorganic electrolytes. In the past, strongly ultraviolet (UV)-absorbing anions such as naphthalenesulfonate, picrate, and also some arylalkylammonium cations have been used as counterions in liquid-liquid chromatography with an organic mobile phase. Nonvisible ionic solutes like acetylcholine, aliphatic amines, dipeptides, and alkyl carboxylates and alkanesulfonates could then be separated and detected by UV absorption through the ion pairing agent. The complexity of these systems with strong requirements on temperature control and careful equilibration

between the two liquid phases has limited the use of this technique. Also, here the introduction of the both universal and selective MS detector has given a new and superior alternative methodology.

In reversed-phase liquid-solid chromatography an indirect detection technique has been applied to charged and noncharged analytes. An ionic component with affinity for the adsorbing phase and with detection properties is included in the aqueous mobile phase. The equilibrium of the detectable ion, the probe, between the mobile and stationary phase will become disturbed by the injection of the analytes into the system. There will be one peak for each of the solutes and at least one additional system peak. When ionic solutes and the probe have opposite charges, peaks eluting before the system peak in the chromatogram have negative direction and those after have positive direction, while this is reversed with ionic solutes of the same charge as the probe. An example is given in **Figure 2**. Apart from the detector response of the probe ion, its fractional coverage of the adsorbent and the relative retention of the solute will influence the detector response. UV-absorbing ions such as naphthalene-2-sulfonate and 1-phenethyl-2-picolinium have been used as probes.

A narrow application field for ion pair chromatography has been the separation of enantiomers in normal-phase liquid-solid systems. Chiral counterions are then used as selectors and their ability to interact with the ionic solute is decisive for the enantioselectivity. (+)-10-Camphorsulfonic acid and a dipeptide derivate, *N*-benzoxycarbonylglycyl L-proline, have been used as ion pairing agents for the resolution of enantiomers of amino alcohols, and quinine and cinchonidine for the separation of enantiomers of chiral carboxylic acids. In recent years, efficient chiral separations employing the ion pair technique on a hydrophobic stationary phase have been demonstrated using different N-blocked dipeptides as counter ions for the resolution of enantiomers of amino alcohols. These systems consist of porous graphitized carbon, Hypercarb, as the solid phase and methanol containing the chiral selector as the mobile phase.

### Selected Applications

Ion pair LC in the reversed-phase mode is the overall dominating separation technique, not least within the biomedical field. Many compounds of interest occur in ionic form or are ionizable, and chromatographic separation can be performed by counterion-aided distribution. The range of applications is extremely wide and includes small hydrophilic aminophenols like catecholamines, carboxylic acids,

hydrophobic tricyclic amines, amino acids, peptides, nucleic acid derivatives, and proteins to mention a few groups of compounds normally present in ionic form and subjected to ion pair chromatography.

Catecholamines can be retained and separated on an octadecyl-bonded phase in the presence of a hydrophobic counterion like C<sub>8</sub>-sulfate in the mobile aqueous phase (Figure 3). For this kind of system it has been shown that the degree of retention is largely correlated to the amount of counterion adsorbed onto the solid phase, forming a charged surface there. The porous graphitic carbon stationary phase is very hydrophobic and particularly suited and used for polar compounds. Reports indicate that on this stationary phase, relative to the silica-based bonded phases, much less of hydrophobic counterions is accumulated on the solid phase, which influences the retention model and also the ranking between different counterions and the effect of the organic modifier. An example of separation of polar guanidino compounds on a graphite column is shown in Figure 4.

The separation of moderate to strongly hydrophobic amines and ammonium compounds on

**Figure 3** Separation of noradrenaline (NA), adrenaline (A), dihydroxybenzylamine (DBH), and dopamine (DA), 0.65 pmol each. Stationary phase: LiChrosorb RP18, 5  $\mu\text{m}$ . silica-bonded phases can often be made with a hydrophilic counterion or just dihydrogenphosphate as both counterion and pH-buffering electrolyte. As mentioned above, many hydrophobic amine solutes showed a chromatographic behavior that was not very satisfactory but it could be corrected by including an aliphatic amine modifier in the mobile aqueous phase. However, the improved properties of modern reversed-phase materials have largely made such precautions unnecessary. For ion pair chromatography of amines, a low pH of 2–3 in the aqueous mobile phase is often used but higher pH, up to neutral, is also possible, e.g., ammonium acetate buffers often used in LC–MS methods.

For the separation of anions of weak protolytes such as carboxylates, a pH close to neutral is chosen to ensure that the solutes are in ionic form. Quaternary ammonium ions such as tetrabutylammonium are most often used as counterions, as in the example given in Figure 5, which shows the separation of benzoic acid and three structurally related carboxylic acids. A mixture of acetonitrile and phosphate buffer of pH 6.0 is the mobile phase. These few applications illustrate the kind of phase systems being used with anionic or cationic counterions. The hydrophobicity

and concentration of the counterion and the nature and content of organic modifier in the aqueous mobile phase are the parameters that can be selected according to the character of the ionic solute and can be combined to affect the selectivity.

## Problems of Analysis

A major application field for reversed-phase LC is ionic or ionizable organic compounds. The addition of a counterion to the aqueous mobile phase to aid the distribution and retention of the ionic solute does not demand ion pair LC of any special precautions or create any separate problems. The use of a guard column, exchanged frequently enough, to protect the

**Figure 5** Separation of carboxylates as ion pairs with tetrabutylammonium (TBA); A, absorbance. Stationary phase: LiChrosorb RP8,  $10 \mu\text{m}$ . analytical column is as obvious as in other forms of LC. Temperature control is advantageous in all types of chromatography. It is necessary in liquid–liquid ion pair chromatography and is crucial in systems with an ionic probe and indirect detection. For regular separations ambient temperature is most often sufficient.

The solvent or solution used for the sample to be introduced into the separation column has to be compatible with the aqueous mobile phase. If it is too strong an eluent and injected in relatively large volumes, peak deformation may occur as in other kinds of chromatography. The addition to the sample solution of a hydrophilic counterion or a strongly competing ionic component of the same charge as the ionic solute may give severe peak distortion, but peak compression under optimized conditions. Column deterioration is probably no more pronounced in ion pair LC than in other systems with bonded stationary phases and mixtures of aqueous buffer solutions and

organic modifiers as mobile phases. Hydrochloric acid is known to be aggressive to all kinds of solid phases and is avoided. Aqueous phase at pH above neutral are believed to affect the bonded phase packing and there are indications that the presence of a quarternary ammonium ion such as tetrabutylammonium potentiates the degradation. Intermittent reports of decreased column stability in ion pair LC can be linked to the nature of injected samples, such as the degree of soluble impurities and microparticulate material in the solution. A guard column should take care of most of this.

From a general point of view, ion pair LC systems can be expected to give a performance and durability comparable to other bonded-phase systems. However, a small proportion of the ion pair reagent may become irreversibly bound to the stationary phase, possibly to free silanol groups, and if so the column cannot be regenerated to its original condition. In practice, this means that once a column has been used for an ion pair separation it should be retained for the specific analysis in question. Attempts to reuse the column for conventional reversed-phase chromatography may lead to unexpected and spurious results.

## Introduction

In the late 1970s, ionic surfactants were added for the first time to polar aqueous–organic mobile phases in reversed-phase liquid chromatography (RPLC) to form ion pairs (IPs). In IP chromatography, surfactant monomers adsorbed on a bonded silica-based stationary phase associate with neutral and ionic solutes, modifying their retention. The concentration of surfactant in the mobile phases is kept below the critical micellar concentration (CMC). In 1980, Daniel W. Armstrong reported the possibility of using

solutions containing surfactants above the CMC for separation purposes. The technique was called pseudo-phase liquid chromatography, adopting later the term micellar liquid chromatography (MLC).

Some qualities of the new technique were outlined in the first descriptions: the relatively low cost, the ease of operation, and the less time required for a complete run. Other qualities were revealed as the technique was developed: the possibility of analyzing solutes presenting a wide range of polarities within a single isocratic run, the high reproducibility of retention times, and their accurate prediction through modeling. The latter feature facilitates the optimization of the separation conditions. The existence of micelles in the mobile phase and the adsorption of surfactant monomers on the stationary phase produce notable changes in the chromatographic

organic modifiers as mobile phases. Hydrochloric acid is known to be aggressive to all kinds of solid phases and is avoided. Aqueous phase at pH above neutral are believed to affect the bonded phase packing and there are indications that the presence of a quarternary ammonium ion such as tetrabutylammonium potentiates the degradation. Intermittent reports of decreased column stability in ion pair LC can be linked to the nature of injected samples, such as the degree of soluble impurities and microparticulate material in the solution. A guard column should take care of most of this.

From a general point of view, ion pair LC systems can be expected to give a performance and durability comparable to other bonded-phase systems. However, a small proportion of the ion pair reagent may become irreversibly bound to the stationary phase, possibly to free silanol groups, and if so the column cannot be regenerated to its original condition. In practice, this means that once a column has been used for an ion pair separation it should be retained for the specific analysis in question. Attempts to reuse the column for conventional reversed-phase chromatography may lead to unexpected and spurious results.

## Introduction

In the late 1970s, ionic surfactants were added for the first time to polar aqueous–organic mobile phases in reversed-phase liquid chromatography (RPLC) to form ion pairs (IPs). In IP chromatography, surfactant monomers adsorbed on a bonded silica-based stationary phase associate with neutral and ionic solutes, modifying their retention. The concentration of surfactant in the mobile phases is kept below the critical micellar concentration (CMC). In 1980, Daniel W. Armstrong reported the possibility of using

solutions containing surfactants above the CMC for separation purposes. The technique was called pseudo-phase liquid chromatography, adopting later the term micellar liquid chromatography (MLC).

Some qualities of the new technique were outlined in the first descriptions: the relatively low cost, the ease of operation, and the less time required for a complete run. Other qualities were revealed as the technique was developed: the possibility of analyzing solutes presenting a wide range of polarities within a single isocratic run, the high reproducibility of retention times, and their accurate prediction through modeling. The latter feature facilitates the optimization of the separation conditions. The existence of micelles in the mobile phase and the adsorption of surfactant monomers on the stationary phase produce notable changes in the chromatographic

behavior (retention, elution strength, peakshape, selectivity, and resolution).

Pure micellar solutions are generally useless as mobile phases, except for highly polar compounds, due to the weak elution strength and poor efficiencies. An organic solvent should be added to decrease the analysis times to acceptable values and enhance efficiencies. However, the concentration of the organic solvent needed is appreciably smaller than in RPLC with conventional organic solvent–water mixtures. In addition, the organic solvent is stabilized by the micellar medium. This decreases the risk of evaporation. Micellar mobile phases are thus stable for a longer time and their toxicity is reduced. Finally, direct injection into the chromatographic system is possible using conventional alkyl-bonded stationary phases. As a result, MLC procedures are faster and more economical.

The term MLC is usually given to the use of micellar mobile phases with RPLC columns. A few examples have been described in other chromatographic modes that use similar mobile phases, with normal or reverse microemulsions, bile salts, and surfactants in supercritical fluids. Also, studies using non-RPLC stationary phases and micellar mobile phases have been reported in size exclusion and gel permeation chromatography. These topics are beyond the scope of this article.

## The Chromatographic System

### The Mobile Phase

Instead of the organic solvent–water mixtures used conventionally in RPLC, the mobile phase in MLC consists of an aqueous solution of surfactant-forming micelles, or a ternary mixture of water, surfactant, and organic solvent (called hybrid micellar mobile phase). In the latter case, the concentration of organic solvent is maintained low enough to permit the formation of micelles; the micellization process is, however, altered.

Several surfactants of different types (nonionic, anionic, cationic, and zwitterionic) have been assayed, but most reported procedures use the anionic surfactant sodium dodecyl sulfate (SDS,  $\text{CMC} = 8.2 \times 10^{-3} \text{ mol l}^{-1}$  at  $25^\circ\text{C}$ ), which is readily available. Other common surfactants are the cationic cetyltrimethylammonium bromide (CTAB,  $\text{CMC} = 9 \times 10^{-4} \text{ mol l}^{-1}$ ), and the nonionic Brij-35 (polyoxyethylene (23) dodecyl ether,  $\text{CMC} = 1 \times 10^{-4} \text{ mol l}^{-1}$ ). Common solvents in RPLC (methanol, ethanol, propanol, acetonitrile, and tetrahydrofuran) are suitable modifiers. Other less polar solvents, such as butanol and pentanol, can

also be added up to useful concentration levels, owing to the solubilizing effect of micelles. Propanol (especially 1-propanol) is the most frequent, although acetonitrile has similar elution strength and usually improves peakshape. Butanol and pentanol, which are stronger solvents, permit the elution of apolar solutes at sufficiently short retention times.

The extreme concentrations of surfactant and organic solvent are imposed by practical limitations in the chromatographic system. The lower concentration of surfactant must be well above the CMC. Its solubility and the viscosity of the resulting mobile phase determine the upper concentration. On the other hand, the concentration of organic solvent is conditioned by the maximal value that ensures the integrity of micelles. For SDS, the maximal concentration of acetonitrile, propanol, butanol, and pentanol should be approximately below 20, 15, 10, and 7% (v/v), respectively.

### The Stationary Phase

Separations are usually carried out in conventional octyl- and octadecylsiloxane (C8 and C18) columns. A significant number of surfactant molecules may be adsorbed on these stationary phases, giving rise to a structure similar to an open micelle. Consequently, column properties change radically, although the subjacent stationary phase (the bonded moiety) still plays a role in the interaction with solutes. Cyano-propylsiloxane-bonded columns are useful for some specific applications. Efficiencies are improved with fluorinated-bonded phases. More recently, ultrawide pore and monolithic octadecylsiloxane columns have been shown to enhance the eluting power of micellar mobile phases.

The amount of adsorbed anionic and cationic surfactants on the column increases rapidly at increasing surfactant concentration in the mobile phase, reaching a plateau nearby the CMC. This is not the case for nonionic surfactants, whose adsorption increases beyond the CMC. Nuclear magnetic resonance studies have indicated that on the densely grafted stationary phase, the hydrophobic chain of anionic surfactants is inserted in the bonded organic layer with the functional group protruding toward the mobile phase (Figure 1A). Cationic surfactants give rise to two kinds of interactions with the stationary phase: hydrophobic association with the alkyl-bonded layer like anionic surfactants, and electrostatic attraction of the positively charged surfactant heads to the residual free silanols, which are buried inside the thickness of the bonded layer (Figure 1B). This explains why the SDS-covered alkyl phases are more polar, with a negative charge, than the CTAB-covered phases, which bear positive charge.

**Figure 1** Solute interactions with stationary phase and micelle in pure MLC systems containing the surfactants: (A) SDS and (B) CTAB.

The adsorption of surfactant monomers changes the stationary phase polarity, structure, surface, and pore volume. Surfactant molecules coat the interior walls of the pores without completely filling them.

Ionic compounds added to the micellar system for pH or ionic strength adjustment increase usually the surfactant adsorption. Organic solvents, in contrast, decrease the amount of adsorbed surfactant. The alkyl chains of propanol and longer *n*-alcohols form on the stationary phase a monolayer similar to that of adsorbed surfactant molecules, with the hydroxyl group oriented toward the aqueous phase. Alcohol and surfactant molecules compete for adsorption sites. For ionic surfactants, the desorbing ability depends on the organic solvent polarity (methanol < ethanol < propanol < butanol < pentanol). Also, the amount of adsorbed surfactant molecules decreases linearly with the organic solvent concentration.

Some care is needed to preserve the column performance for long time periods of intensive MLC use, which can be comparable or even longer than in conventional RPLC. First, since most micellar solutions are able to dissolve minute amounts of silica, the mobile phase should be saturated in silica by placing a short precolumn before the injection valve. Second, the micellar solution should never stay motionless in a chromatographic system to avoid the formation of surfactant crystals that can clog the

system or ruin the column. When the system is not being used, the flow can be reduced to a minimal value (e.g.,  $0.1 \text{ ml min}^{-1}$ ). Finally, before stopping the flow, the column should be cleaned with water to later allow the passage of pure methanol or a 75:25 methanol–propanol mixture for a few minutes. Operating in this way, the layer of SDS monomers can be completely stripped off the stationary phase. CTAB and Brij-35 cannot be removed so easily. With convenient experimental caution, hundreds of injections can be made without modification of the chromatographic system or pressure buildup.

The existence of a plateau of adsorbed ionic surfactant above the CMC permits rapid analyses using a micelle gradient. Beyond the CMC, changes in total surfactant concentration only change the concentration of micelles in the mobile phase; the stationary phase is not affected. This means that the initial conditions can be recovered without re-equilibration time. However, normally, the particular elution strength behavior of MLC makes gradient elution unnecessary.

## Partitioning Behavior

MLC is a good example of the use of secondary equilibria in liquid chromatography. Solutes are partitioned between the mobile and stationary phases,

which are modified by the presence of surfactant monomers and micelles. Depending on polarity and steric factors, solutes can remain outside the micelle, associate to the polar head of the surfactant, form a part of the outer palisade layer, or penetrate into the micelle core. Organic solvents added to the micellar solution experience the same interactions: the association of acetonitrile and methanol with micelles is weak, while butanol and pentanol are inserted in the intermonomer spaces of the micelle palisade.

Neutral solutes interact hydrophobically with micelles. An increase in the concentration of surfactant in the mobile phase results in decreased retention. Water-insoluble apolar solutes exhibit a large affinity for the micelles and the surfactant-coated stationary phase, and, consequently, can be only transported between them by direct transfer. By addition of organic solvent to the mobile phase, the solubility of the apolar solutes increases and this transfer mechanism loses importance with regard to the usual two-step mechanism (micelle–bulk solvent and bulk solvent–stationary phase) (Figure 1).

Charged solutes experience hydrophobic and electrostatic interactions with ionic surfactants. Two distinct situations are possible:

- Charges on solute and surfactant are of the same sign. Electrostatic repulsion from the surfactant-modified stationary phase should cause a low retention (the solute may be even eluted with the void volume), unless sufficiently strong hydrophobic interaction is established. A particular behavior has been observed with methylsiloxane (C1) and cyanopropylsiloxane-bonded phases, where the amount of adsorbed surfactant is low: repulsion of solutes from micelles is dominant and the retention increases at increasing micelle concentration (antibinding behavior). In this case, the electrical double layer surrounding the micelles can be narrowed in a solution containing higher concentration of ions, which facilitates the approximation of the solute to the micelle assembly to establish hydrophobic interactions. By increasing the ionic strength, antibinding solutes can thus adopt nonbinding or even binding behavior.
- Charges on solute and surfactant are opposite. Electrostatic and hydrophobic interactions with the stationary phase may be sufficiently large to offset the increase in micelle attraction, and retention will be strong.

## Correlations between Retention and Polarity

MLC has demonstrated to be useful for measuring the polarity of compounds. The regular linear

increase in  $\log k$  with the number of carbon atoms,  $n_C$ , in a homologous series, observed in aqueous–organic RPLC is not usually valid with micellar mobile phases;  $k$  versus  $n_C$  is linear instead. This behavior has been explained by the location in the micelle of different members in the homologous series. The more hydrophobic homologues tend to locate in more apolar microenvironments, experiencing smaller change in polarity upon transfer from the micelle to the stationary phase.

Good correlation has been found between retention in MLC and the logarithm of octanol–water partition coefficient,  $\log P_{o/w}$ , for series of neutral compounds of diverse polarities. The type of general relationship ( $\log k$  versus  $\log P_{o/w}$  or  $k$  versus  $\log P_{o/w}$ ) seems to depend on the selected set of compounds and the characteristics of both the mobile and stationary phases. The linearity is improved by addition of alcohols. The organic solvent apparently provides an environment closer to the octanol–water mixture than pure micellar systems. Correlation of retention with  $\log P_{o/w}$  is poorer for ionizable compounds, due to the extra ionic interactions. However, acceptable correlation has been found for groups of basic compounds in acidic mobile phases of anionic surfactant, where the positively charged protonated species dominate. The retention of cationic solutes is superior than expected from the correlation established for nonionizable compounds, which are retained due only (or mainly) to hydrophobic interactions.

Alternatively, retention can be predicted from solute  $\log P_{o/w}$  values. The most suitable organic solvent to be used as modifier of the mobile phase should be chosen according to the polarity of the eluted compound. For SDS, a low propanol content ( $\sim 1\%$ , v/v) is useful to separate compounds with  $\log P_{o/w} < -1$ , such as amino acids. A larger amount of propanol ( $\sim 5\text{--}7\%$ ) is needed for compounds in the range  $-1 < \log P_{o/w} < 2$ , such as diuretics and sulfonamides. Other alcohols ( $< 10\%$  butanol or  $< 6\%$  pentanol) are required for apolar compounds with  $\log P_{o/w} > 3$ , such as steroids. This rule of thumb is, however, not always valid: propanol is too weak for cationic solutes, such as phenethylamines ( $0 < \log P_{o/w} < 1.7$ ) or  $\beta$ -blockers ( $1 < \log P_{o/w} < 3$ ). For these compounds, the additional electrostatic attraction to the anionic surfactant molecules adsorbed on the stationary phase makes a stronger solvent necessary.

Micelles are recognized as simple biomembrane models. Biomembrane and micelles have amphiphilic properties and are anisotropic, providing hydrophobic and electrostatic interaction sites. MLC combines the unique characteristics of micelles and the capabilities of RPLC in quantitative retention–activity relationships studies.

## Effect of pH on Retention

Chromatographic retention of ionizable compounds depends on the pH of the mobile phase. Micelles and organic solvent shift the protonation equilibria, due to the modification of the polarity of bulk solvent and the association of solutes with micelles. Since the intrinsic retention of both acid–base species is different, a sudden change in retention time will happen at pH values close to the logarithm of the apparent protonation constant in the mobile phase medium,  $K'_H$ . The full protonation process covers several pH units and is shifted more or less depending on the concentrations of surfactant and organic solvent. The change in retention is not properly observed when the working pH of the column is narrow (e.g., pH 3–7 for conventional alkyl-bonded stationary phases). In this case, retention versus pH plots may show different patterns (Figure 2).

Usually,  $K'_H$  diminishes as the organic solvent concentration increases. For ionic surfactants, solute–surfactant electrostatic interactions are responsible for the shift in sign in  $K'_H$  at increasing surfactant concentration. These interactions also explain the sign in the trend of the  $k$ –pH dependence, which is sigmoidal and resembles conventional acid–base titration curves. The observed behaviors indicate that the interaction of solutes with the surface of the surfactant-modified stationary phase is stronger than that with micelles.

For weak bases having neutral acidic and anionic basic species (or weak bases having cationic acidic and neutral basic species),  $K'_H$  increases with

**Figure 2** Retention versus pH plots for: (A) xipamide, (B) ethacrynic acid, and (C) tyrosine. Chromatographic system: ODS-2/0.10 mol l<sup>-1</sup> SDS/4% (v/v) 1-propanol.

surfactant concentration for anionic surfactants, since the acidic species is stabilized by interaction with micelles and adsorbed monomers. Also, retention decreases with pH, due to the weaker association of the basic species with the surfactant-modified stationary phase (Figure 2). The shift in  $K'_H$  to higher pH benefits the observation of the maximal retention (the retention of the acidic species) within the operable limits of silica-based columns. When a cationic surfactant is used instead, both the shift in  $K'_H$  and the  $k$  versus pH dependence are opposite to those observed for anionic surfactants, since cationic surfactant molecules stabilize the basic species.

The pH of the micellar mobile phase is usually buffered using the phosphoric or citric acid–base system. Potassium ion cannot be used with SDS as potassium dodecyl sulfate precipitates from aqueous solutions. Only one peak is observed for each solute in the chromatograms because acid–base equilibria are much faster than solute–micelle or solute–stationary phase dynamics.

## Modeling of Retention

### Pure Micellar Mobile Phases

The retention behavior is the final result of the competition of the equilibria existing in the separation system. In MLC, solutes partition between three environments: water, micelle, and stationary phase (Figure 1). If the solute interacts with the micelle, retention is explained by

$$\frac{V_e - V_0}{V_s} = \frac{k}{\phi} = \frac{P_{AS}}{1 + v(P_{AM} - 1)[M]} \quad [1]$$

where  $V_e$  represents the total volume of mobile phase needed to elute the solute from the column,  $V_s$  the volume of active surface of the stationary phase,  $V_0$  the column void volume,  $\phi = V_s/V_0$  the phase ratio,  $v$  the partial specific volume of surfactant monomers in the micelle,  $P_{AS}$  and  $P_{AM}$  are the partition coefficients between water and stationary phase, and between water and micelle, respectively, and  $[M]$  is the concentration of micellized surfactant (total concentration of surfactant minus CMC).

For  $[M] = 0$ , eqn [1] reduces to the partition equation of aqueous–organic RPLC:

$$V_e = V_0 - V_s P_{AS} \quad [2]$$

A more practical model can be written by considering the interactions of solute inside the column in terms of association equilibria of solute in bulk solvent, with stationary phase binding sites and

surfactant monomers in micelles:

$$k = \frac{\phi P_{AS}}{1 + K_{AM}[M]} \quad [3]$$

which results in the following linear model:

$$\frac{1}{k} = \frac{1}{K_{AS}} + \frac{K_{AM}}{K_{AS}}[M] = c_0 + c_1[M] \quad [4]$$

where  $K_{AS} = \phi P_{AS}$ ;  $K_{AM}$  is the association constant of the solute with a surfactant monomer in the micelle and should be multiplied by the aggregation number to be referred to the whole micelle. MLC provides a convenient mode of estimating  $K_{AM}$ , since solute concentration need not be known, the impurities in the sample are separated, and the chromatographic process makes the simultaneous determination of the constants for several solutes possible.

Equations [1], [3], and [4] have been checked to be valid for apolar, uncharged polar, and ionic solutes chromatographed with anionic, cationic, and nonionic surfactants, in octylsiloxane- (C8), octadecylsiloxane- (C18), and cyanopropylsiloxane-bonded columns.

### Hybrid Micellar Mobile Phases

The addition of organic solvent to the micellar mobile phase shifts the partition equilibria of the solute in bulk solvent with both the stationary phase and the micelle. The retention is described by

$$k = \frac{K_{AS}[(1 + K_{SD}\phi)/(1 + K_{AD}\phi)]}{1 + K_{AM}[(1 + K_{MD}\phi)/(1 + K_{AD}\phi)][M]} \quad [5]$$

$\phi$  being the volumetric fraction of organic solvent. The constants  $K_{AD}$ ,  $K_{SD}$ , and  $K_{MD}$  measure the relative variation in the concentration of solute in bulk water, stationary phase, and micelle, respectively, due to the diminution in bulk solvent polarity and the modification of the stationary phase and micelle produced by the organic solvent. The  $K_{SD}$  term is only needed for highly apolar solutes, which are strongly associated to the stationary phase. In other cases,  $K_{SD} = 0$  and eqn [5] can be simplified to

$$k = \frac{1}{c_0 + c_1[M] + c_2\phi + c_{12}[M]\phi} \quad [6]$$

The analogous effects of organic solvent on both microenvironments (stationary phase and micelle) are evident in the parallel variations of solute-stationary phase and solute-micelle partition coefficients, as the concentration of organic solvent changes.

### Simultaneous Effect of Surfactant, Organic Solvent, and pH

Very often, chromatographic separations are carried out in a buffered medium. In this case, eqns [4]–[6] are appropriate to describe the retention of ionizable solutes. For compounds exhibiting acid–base behavior, retention in pure micellar medium is a weighted mean of the retention of the basic and acidic species. At varying pH,

$$k = \frac{k_A + k_{HA}K'_Hb}{1 + K'_Hb} \quad [7]$$

where  $k_A$  and  $k_{HA}$  are the retention factors of the basic and acidic species, and  $b$  is the concentration of hydrogen ion. When the simultaneous effect of the three factors (surfactant, organic solvent, and pH) is considered, the retention is given by

$$k = \frac{K_{AS} \frac{1 + K_{SD}\phi}{1 + K_{AD}\phi} + K_{HAS} \frac{1 + K_{HSD}\phi}{1 + K_{HAD}\phi} K_Hb}{\left(1 + K_{AM} \frac{1 + K_{MD}\phi}{1 + K_{AD}\phi} [M]\right) + \left(1 + K_{HAM} \frac{1 + K_{HMD}\phi}{1 + K_{HAD}\phi} [M]\right) K_Hb} \quad [8]$$

$K_{AS}$ ,  $K_{AM}$ ,  $K_{SD}$ ,  $K_{AD}$ , and  $K_{MD}$  are equilibrium constants associated to the basic species, and  $K_{HAS}$ ,  $K_{HAM}$ ,  $K_{HSD}$ ,  $K_{HAD}$ , and  $K_{HMD}$  are constants associated to the acidic species.

### Peak Shape

The thick surfactant film formed on the surface of the organic bonded layer is partially responsible for the loss of efficiency (i.e., broad and tailing peaks) observed when pure micellar mobile phases are used, with regard to aqueous–organic mixtures, which is especially true for apolar compounds. Peak Shape deteriorates at larger surfactant concentration. This is a major drawback that hindered the development of MLC. The addition of a small amount of propanol was first proposed to remediate this problem. Other organic solvents, such as butanol, pentanol, and acetonitrile, were later used with different degrees of success. Efficiency increases in some cases dramatically, and for polar compounds it becomes often similar (or eventually larger) to that achieved in classical RPLC. Peak tailing is also partially or totally suppressed.

The reason for the favorable behavior produced by the addition of organic solvent is the reduction of the viscosity and thickness of adsorbed surfactant on the stationary phase, and the increase in solute–micelle exit rate constants. This enhances the rate of solute mass-transfer between bulk solvent and both the stationary phase and micelles. Higher temperature decreases also the viscosity, and increases the chemical reaction rates.

**Figure 3** Chromatogram of a mixture of 14  $\beta$ -blockers. Chromatographic systems: (A) ODS-2/0.10 mol l<sup>-1</sup> SDS/15% (v/v) 1-propanol, and (B) X-Terra MS/15% (v/v) acetonitrile. Compounds: (1) atenolol, (2) sotalol, (3) carteolol, (4) nadolol, (5) pindolol, (6) acebutolol, (7) celiprolol, (8) esmolol, (9) timolol, (10) bisoprolol, (11) labetalol, (12) oxprenolol, (13) propranolol, and (14) alprenolol.

Basic compounds are difficult to quantify by classical RPLC due to the ionic interaction of the positively charged species with free silanol groups of the packings. Ion exchange can be avoided, at least partially, by lowering the pH of the mobile phase to suppress the ionization of silanols. This process can be also blocked by addition of amine modifiers (mainly tertiary amines) that associate to silanol sites. Efficiency and peak tailing for several basic compounds, such as phenethylamines, tetracyclines, and  $\beta$ -blockers, eluted from conventional octadecylsiloxane columns with hybrid SDS mobile phases, are thus similar to those achieved with polymeric columns and aqueous-organic mixtures (Figure 3). The thinner surfactant layer on the modified column, in the presence of organic solvent, permits good diffusion of solutes. Also, the interaction of the protonated basic compound with the anionic heads of adsorbed SDS monomers reduces its penetration depth into the bonded phase. The kinetics of this electrostatic association seems to be easier than ion-exchange processes involving the silanols on the silica surface.

## Separation Performance

In MLC, the retention behavior (elution strength and selectivity) can be quite different from the observed

**Figure 4** Chromatogram of a mixture of eight steroids. Chromatographic systems: (A) ODS-2/0.12 mol l<sup>-1</sup> SDS/6% (v/v) 1-pentanol, and (B) ODS-2/52% (v/v) acetonitrile. in classical RPLC, even after the addition of an organic modifier. The range of interactions provided by MLC is by far superior to that in aqueous-organic systems. This feature confers micellar mobile phases the ability of making cationic, anionic, uncharged polar, and apolar solutes compatible within the same chromatographic run. Furthermore, perhaps the main strength of MLC lies in the capability of performing the isocratic separation of mixtures of compounds exhibiting a relatively wide range of polarities (Figure 3).

The best resolution is usually found at low surfactant concentration due to the concurrence of longer retention times and better efficiencies. In contrast, moderate or high organic solvent concentrations (with the limitation of maintaining the micelles) are required, due mainly to the improvement in peak shape. For polar compounds, the elution strength of the surfactant is larger or similar to the organic solvent; the opposite situation is found for apolar compounds, which can be eluted at sufficiently low retention times using a small amount of butanol or pentanol in the micellar mobile phase (Figure 4).

The selectivity can be maximized by choosing the nature and adequate concentration of both the surfactant and organic modifier and, occasionally, the pH. The larger possibilities of tuning the

selectivity, together with the more even distribution of peaks in the chromatograms, compensate often the poorer efficiencies achieved in MLC, making this technique competitive against classical RPLC. Actually, both chromatographic modes show complementary resolving capabilities. Equations [3]–[8] are useful for predicting the retention. Optimizations based on these models can be carried out using economical experimental designs.

## Analytical Applications

Most reported applications correspond to the assay of drugs in pharmaceutical preparations and physiological fluids. Some examples are given in **Table 1** and **Figure 5**. Micellar solutions can be used to dissolve samples or extract analytes. Apolar and polar compounds, derivatization reagents, and products can be co-solubilized. These media can also induce favorable shifts in the equilibrium constants and expedite reactions through micellar catalysis. Micelles improve the analytical performance of various spectroscopic (ultraviolet–visible spectrophotometry, fluorimetry, phosphorimetry, and atomic absorption) and electrochemical (amperometry) detection methods, by increasing the sensitivity, modifying the selectivity, and overcoming some problems associated with the use of aqueous–organic solvents. An interesting recent example is the use of MLC with nonionic surfactant to separate amino acids or cholesterol derivatives with postcolumn immobilized enzyme reactors. The micellar phases are gentler for the enzyme activity than aqueous–organic mobile phases or aqueous buffers.

One of the main appealing factors of MLC is the possibility of determining drugs in physiological fluids in a few minutes, without the need of previous separation of the proteins present in the samples. Micelles bind to proteins releasing bound drugs, whereas the proteins rather than precipitating on the column are solubilized and swept away, eluting with or shortly after the solvent front. However, although hundreds of repetitive serial injections are possible, the sample should be diluted when possible before performing the direct injection to keep the column operative for a longer time. The anionic SDS is the most common surfactant in these analyses, but the nonionic Brij-35 can also be employed. Cationic surfactants are not compatible because they cause the precipitation of proteins.

### Introduction

Size-exclusion chromatography (SEC) is the conventional name for a separation method used most frequently for the fractionation and analytical characterization of macromolecules of biological or synthetic origin and less frequently for the separation of colloidal particles. The history of SEC began in the late 1950s with the observation that proteins can be separated on porous cross-linked dextran gels, swollen in aqueous media. The first separation of a synthetic polymer by SEC was described by Vaughan. Moore was the first to separate polymers in a column using cross-linked polystyrene gel. The invention of small porous particles with a typical diameter between 1 and 10  $\mu\text{m}$  brought about an important technological improvement in SEC. The consequent miniaturization of the columns allowed the reduction of the analysis time to minutes or even to tens of seconds.

The development of this separation method is reflected by the numerous names that have been given to this process; for example, gel filtration, gel chromatography, gel filtration chromatography, gel exclusion chromatography, gel permeation chromatography, restricted diffusion chromatography, size separation chromatography, and molecular sieve chromatography. The term SEC, which has been most frequently used in the recent literature, describes very concisely the basic mechanism governing the separation. Nevertheless, this mechanism, separating the species according to their effective dimensions in the solution, is often complicated by other interactions that can, in some instances, make the separation more efficient but can also deteriorate it. This fact must be taken into consideration when selecting the experimental conditions in SEC.

Theoretical bases of the separation and dispersion in SEC are briefly reviewed in order to allow an understanding of the performances of this method when applied to the separation and characterization of macromolecular or particulate species. Among various retention mechanisms theoretically describing the separation, the most general thermodynamic approach represents an advantage due to the fact that it covers the cases where the entropy-driven size exclusion is not dominating the separation of the retained species and the enthalpy-driven interactions

also take place in the chromatographic system. The SEC method can be used not only for purely separation purposes but also for the quantitative characterization of the molar mass or size of the separated species, provided an accurate calibration procedure of the separation system and a correction for the zone broadening are applied.

### Fundamentals

The basic principle of the SEC can be best explained with the use of **Figure 1**. The separation is considered as a specific type of distribution of the separated species (solute) between the solvent filling the pores of the column packing particles (stationary phase) and the solvent outside the particles (mobile phase). The total volume of a packed column,  $V_T$ , is the sum of the total volume of all pores,  $V_p$ , of the volume of the particles matrix,  $V_m$ , and of the interstitial volume,  $V_0$ , outside the particles:

$$V_T = V_m + V_0 + V_p \quad [1]$$

The biggest solute molecules are excluded from the penetration into the pores and move with the mobile phase only in the interstitial volume. Their elution (retention) volume is thus equal to  $V_0$ . The small molecules (including the mobile phase) can penetrate all available pores and their retention volume is the sum ( $V_0 + V_p$ ). The solute molecules of intermediate size can, according to the ratio of their size to the pore size, penetrate a part of the pores while they are excluded from another part. Their retention volume lies within the above limit volumes. Consequently,

**Figure 1** Schematic representation of a chromatographic column for SEC with the void volume between the spherical particles of the column packing and the structure of one porous particle with the pore and matrix volumes.

the retention volume  $V_R$  of a uniform size solute species is

$$V_R = V_0 + K_{SEC} V \quad [2]$$

where  $K_{SEC}$  is a formal distribution coefficient that can also be written in a standard thermodynamic form as

$$K_{SEC} = \frac{c_p}{c_0} \quad [3]$$

where  $c_p$  and  $c_0$  refer to the solute concentrations in the pores and in the interstitial volume, respectively. For the solute molecules that are excluded from the pores,  $K_{SEC} = 0$ . For the molecules that can penetrate the pores and where no other interactions occur in addition to size exclusion,  $0 < K_{SEC} < 1$ . Totally penetrating molecules exhibit  $K_{SEC} = 1$ . Whenever  $K_{SEC} > 1$ , other interactions (e.g., adsorption) participate in the separation mechanism. The thermodynamic interpretation of the distribution coefficient  $K_{SEC}$ , given in the following paragraph, allows one to explain accurately the dependence of  $K_{SEC}$  on the molar mass or size of the solute molecules.

## Theory of Retention

A number of theoretical approaches explained the retention by a simple size-exclusion mechanism presented in the Introduction. Such explanations were associated with more or less complicated pore shapes that were considered as a system of cylindrical, conical, etc., holes that spherical solute molecules can penetrate. The size distribution of the pores was not given much importance. Nevertheless, experiments whose objective was to correlate the molar mass dependence of the retention volume of different solute molecules with the pore size distribution curves did not provide satisfactory results. Although more sophisticated models of this type were more successful when compared with the experiments, they are not considered now as they are not sufficiently general and do not accurately describe the physical reality.

The above-mentioned mechanistic models of separation were based on the assumption that the time necessary to transport the solute molecules between the phases is much shorter than the time spent by them at a given position inside the column. To overcome the difficulty to explain the differences in  $K_{SEC}$  measured under static and dynamic conditions, a mechanism of restricted diffusion has been suggested. Unfortunately, the restricted diffusion model is incoherent with the independence of the  $K_{SEC}$  on the flow rate and temperature observed within a wide range of experimental conditions.

In the so-called hydrodynamic models, the porous structure is approximated by a system of open cylindrical capillaries of different diameters. A flow velocity profile formed inside, combined with the stochastic movement of the solute molecules, results in different average velocities of the molecules transported down the capillary. Larger molecules are eluted at higher average velocities. The model assumes that the percolating solvent can pass through the pores. Such a situation, nevertheless, cannot be true, especially with polymeric gels. Even if a flow through the open pores is possible, the flow rate that is proportional to the fourth power of the radius of the capillary should be too low with respect to the ratio of the diameter of the capillaries in the interstitial volume to that inside the pores, which is  $\sim 10$ – $1000$ .

The stochastic models were developed by calculating the probability with which the solute molecules can penetrate the pores. A comparison of these theoretical models with some experimental data has rendered good agreement.

The above-mentioned mechanisms of SEC separation represent the evolution of theoretical opinion and can still, under specific conditions, provide an explanation of the particular phenomena emerging in experimental SEC. More details on these theories together with the corresponding references can be found in references cited in the Further Reading section. The most general theoretical concept is based on the thermodynamic approach. All transport phenomena in SEC are supposed to take place near the thermodynamic equilibrium. Thus, the equilibrium concentration distribution of the solute represents a good approximation of the actual state of the system. It holds for a change in the Gibbs free energy for a displacement of the mole of a species between two locations at a constant temperature  $T$  and pressure  $P$ :

$$dG = dH - T dS \quad [4]$$

where  $H$  and  $S$  are enthalpy and entropy, respectively. It holds for an exchange of mass due to the separation processes:

$$dG = \left( \frac{\partial G}{\partial n_i} \right)_{T,P,n_{j \neq i}} dn_i \quad [5]$$

where  $dn_i$  is the number of the species  $i$  entering the system. The chemical potential is

$$\mu_i = \mu_i^\circ + RT \ln c_i \quad [6]$$

The use of the concentration  $c_i$  instead of the activity is justified by the very low concentrations concerned. It holds for the equilibrium between the stationary

and mobile phases that  $dG = 0$  and

$$\mu_i^m = \mu_i^s \quad [7]$$

$$\frac{c_{si}}{c_{mi}} = \exp\left(\frac{\Delta\mu_i^\circ}{RT}\right) = \exp\left(\frac{-\Delta H^\circ}{RT}\right) \exp\left(\frac{\Delta S^\circ}{R}\right) \quad [8]$$

The enthalpic term in eqn [8] can be considered as a partition coefficient  $K_p$ , whose value is unity ( $\Delta H^\circ = 0$ ) if the size exclusion is the only interaction of the solute molecules with the column packing. If the adsorption and/or partition of the solute takes place in the chromatographic system,  $K_p > 1$  ( $\Delta H^\circ$  is negative), or if an incompatibility between the solute and the column packing exists,  $K_p$  lies between zero and unity ( $\Delta H^\circ$  is positive). Consequently, the entropic term in eqn [8] represents the distribution coefficient  $K_d$  of pure size exclusion.  $K_d$  acquires values between zero and unity and, in agreement with the experimental findings, is independent of the temperature. Hence, the distribution coefficients can be re-defined as

$$K_p = \exp\left(\frac{-\Delta H^\circ}{RT}\right) \quad [9]$$

$$K_d = \exp\left(\frac{\Delta S^\circ}{R}\right) \quad [10]$$

If  $K_p \neq 1$ , the nonexclusion interactions take place in the separation mechanism. The absence of such interactions requires the SEC to be performed under conditions of only entropic, size exclusion interactions. In such a case,  $K_p = 1$  and  $K_d = K_{SEC}$ . It follows from this thermodynamic approach that the distribution coefficient depends on the chemical character of the solute molecules and that of the solvent, as well as on the matrix constituting the porous particles.

Several other theories were proposed, each one being more or less conforming with a particular case and sometimes with a singular case, such as the flexible, noninteracting macromolecular chains or rigid, freely rotating macromolecules, etc., retained in the pores of a column packing. Each particular approach explains (often in a very sophisticated manner) the retention of the considered species on a well-defined porous structure. The problem is that none of these theories can be applied to resolve the practical analytical question: how to associate the experimental retention data obtained on a given chromatographic column to the molecular characteristics of the separated species.

In practice, the only viable method is the calibration of the separation system with a series of molecules, macromolecules, etc., of the well-known molar masses and chemical nature and the use of the

calibration function to calculate the molar mass of an unknown sample from its chromatogram. From this point of view, the above described general thermodynamic approach is very useful because it provides a real possibility to understand the practical problems of the separations by SEC, the role of the dominating size-exclusion mechanism, and also the importance of the casual enthalpy-driven (non-size exclusion) interactions that are almost always present at different degrees. This approach is justified by the increasing applications of the SEC to the separation and characterization of more and more complex macromolecules of natural biological or synthetic origin, associating systems such as the micelles, polyelectrolytes, etc. However, the references to the existing theoretical models can be found in the literature dealing with SEC and its practical use for analytical purposes.

## Theory of Zone Broadening

The zones of the separated species migrating down the column undergo dynamic processes and mechanisms that are caused by the natural entropic tendency to disperse any concentration gradient formed. A short pulse of a solution of uniform solute species introduced into the column is subject to a broadening during the elution. Consequently, the concentration distribution of the solute inside the column changes permanently from the initial distribution at the moment of the injection until the final one at the end of the elution. The exhaustive theory of the zone dispersion in chromatography is frequently described in the specialized literature. This section covers the explanation of the basic principles of zone-broadening mechanisms necessary to understand and interpret correctly the experimental results of SEC.

It follows from the general theory of chromatography that the elution curve  $F(V)$  (chromatogram) of a uniform solute can be approximated by a Gaussian distribution function:

$$F(V) = \frac{1}{\sqrt{2\pi}\sigma^2} \exp\left(\frac{(-1/2)(V - V_R)^2}{\sigma^2}\right) \quad [11]$$

where  $\sigma$  is the standard deviation of the Gaussian distribution function. The graphical representation of a model chromatogram is shown in Figure 2. The Gaussian shape of the elution curve is at the origin of the definition of the height equivalent to a theoretical plate,  $H$ :

$$H = L \left( \frac{\sigma}{V_R} \right)^2 \quad [12]$$

**Figure 2** Schematic representation of a model SEC chromatogram characterized by the retention volume of the peak maximum and the standard deviation of the peakwidth.

which is used to describe the efficiency of the chromatographic column. Lower its value, the more efficient is the column, because the broadening of the zone is less important. The physical meaning of  $H$  follows from the random-walk theory of chromatography. In terms of this theory, several processes contribute to the final width of the elution curve. This can quantitatively be described by

$$H = \frac{B}{v} + \frac{C}{v} + \sum \frac{1}{1/A_i + 1/(C_{mi}v)} \quad [13]$$

where  $v$  is the velocity of the mobile phase in the column. The first, second, and third terms on the right-hand side of eqn [13] describe, respectively, the effect of the longitudinal diffusion, nonequilibrium effects in the stationary phase, and eddy diffusion and nonequilibrium effects in the mobile phase. The diffusion coefficient  $D$  of the solute molecules in the pores is reduced by an obstructive factor  $\gamma_s$  and by a factor  $\gamma_0$  in the interstitial volume. Hence,  $B$  is given by

$$B = 2\gamma_0 D + \frac{2\gamma_s D(1 - v_R/v)}{v_R/v} \quad [14]$$

where  $v_R$  is the velocity of the zone of the retained solute molecules. It holds for the spherical particles of the diameter  $d_p$  of the column packing:

$$C = \frac{v_R/v}{30} (1 - v_R/v) \frac{d_p^2}{\gamma_s D} \quad [15]$$

The terms  $1/A_i$  and  $1/C_{mi}v$  describe the effect of the eddy diffusion and nonequilibrium in the mobile phase, respectively. The contribution to zone broadening due to the eddy diffusion is dominating at high flow rates. The importance of both these terms is related with the particle size distribution (PSD) and with the homogeneity of the column packing or, in other words, with the relative differences in the flow

**Figure 3** Schematic representation of a chromatographic column with various scales of the relative flow velocity differences: a – trans-particle scale; b – trans-channel scale; c – short-range interchannel scale; d – long-range interchannel scale; e – trans-column scale; f – trans-pore scale.

velocities caused by the flow velocity profiles and irregularities in the column packing. Five different  $A_i$  and  $C_{mi}$  terms can be distinguished according to the scale, over which the flow velocity differences are considered, namely, trans-channel, trans-particle, short-range interchannel, long-range interchannel, and trans-column. The schematic representation of the domains corresponding to these five different contributions is shown in Figure 3. The trans-particle scale (a) takes into account the average ratio of the maximum to the average flow velocities across the particles under the condition that there is no negligible flow through the open pores (f) in the particles. The trans-channel scale (b) takes into account the average ratio of the maximum to the average flow velocities in the channels forming the interstitial volume and the three later contributions concern the heterogeneity of the average flow velocities on various distances across the column, short-range interchannel (c), long-range interchannel (d), and trans-column (e) scales. All these contributions are additive, as demonstrated by the third term in eqn [13].

In the absence of the specific interactions of the solute with the column packing, the chemical nature of the packing has no effect on the zone broadening and the effect of the pore size distribution is negligible. The effect of the temperature is related exclusively with the changes of the mobile phase viscosity and, consequently, with the changes of the solute diffusion coefficients. The effect of the solute molar mass on the efficiency is related to the mobility of the macromolecules in the solution that decreases with decreasing solute diffusion coefficient. The chromatograms of high molar mass solute exhibit a tendency to an important asymmetry. The presented theoretical model agrees well with the experimental results. A typical shape of the  $H$  versus  $v$  dependence is shown in Figure 4.

**Figure 4** Schematic representation of the dependence of the height equivalent to a theoretical plate,  $H$ , on the velocity of the mobile phase,  $v$ .

## Information Contents of a Chromatogram

The position of the maximum, the width, and the whole shape of the chromatogram contains information on various processes related with the separation and dispersion, as demonstrated in the above discussion. As long as a retained species is uniform (monomolecular), which means that the sample does not exhibit a molar mass distribution (MMD) or that the MMD is negligibly narrow, the position of the chromatogram maximum can be simply related with the molar mass or size of the sample and the calibration graph, such as that shown in **Figure 5**, can easily be constructed by relating, e.g., the molar mass to the retention volume of a series of standard samples. It has to be stressed, however, that the molar mass is not a universal molecular characteristic on the basis of which the calibration curve obtained with the use of polymer standards of a given chemical composition and structure is applicable to other polymers. It is rather a product of the molar mass and intrinsic viscosity,  $M[\eta]$ , which is proportional to the hydrodynamic volume of a macromolecular chain in solution; that is, the effective molecular size governing the separation under the conditions that the entropy-driven size exclusion is the dominating mechanism.

The width of each particular peak of a chromatogram, in the case that the individual peaks are not overlapping, characterizes only the dispersion phenomena and thus the efficiency of the SEC column. The molar mass or size of the separated species can easily be determined from the position of the maximum of each particular peak. Such a situation is typical for either low molar mass molecules or for some macromolecules of biological origin. Most of the polymers, including the natural ones, are not uniform with respect to their molar mass or size but exhibit the MMD or the PSD. In these cases, the

**Figure 5** Schematic representation of a calibration graph of the column for SEC.

resulting chromatogram represents a superposition of all overlapping peaks, each one corresponding to a particular molar mass, and of the zone broadening. Such a situation is schematically represented in **Figure 6** showing a simplified model chromatogram of a polydisperse macromolecular sample.

As a result, in order to extract accurate information concerning the average molar mass and MMD of a polydisperse sample from the SEC data, the contribution of the dispersive processes should be subtracted from the raw chromatogram. Such a procedure is mathematically rather complex but, fortunately, most of the producers of the SEC chromatographs include the corresponding software into the data treatment computer pack. A simplified explanation of the correction procedure is given here.

As mentioned in preceding paragraphs, the raw chromatogram of a polydisperse sample represents a convolution of the separation and of the zone broadening. This fact can be described mathematically by

$$h(V) = \int_0^\infty g(Y)G(V - Y) dY \quad [16]$$

where  $h(V)$  represents the raw chromatogram,  $g(Y)$  is the chromatogram corrected for the zone broadening, and  $G(V, Y)$  is the spreading function or, in other words, the detector response to a uniform species having the elution volume  $Y$ . The spreading function can be, in agreement with the above presented theory of zone broadening, approximated by a Gaussian function:

$$G(V, Y) = (1/(2\pi\sigma_s^2))^{1/2} \exp[-(V - Y)^2/(2\sigma_s^2)] \quad [17]$$

where the standard deviation  $\sigma_s$  should be independent of the retention volume. Whenever  $\sigma_s$  depends on

**Figure 6** Schematic representation of the superposition of five different molar mass (or size) separated species resulting in an overall chromatogram.

**Figure 7** Schematic representation of the difference between a raw chromatogram and the chromatogram corrected for the zone broadening.

the retention volume, the relationship to be applied is

$$h(V) = \int_0^{\infty} g(Y) [1 / (2\pi(\sigma_s(Y))^2)]^{1/2} \times \exp[-(V - Y)^2 / (2(\sigma_s(Y))^2)] dY \quad [18]$$

Equation [17] or [18] can be solved numerically in order to obtain the chromatogram corrected for zone broadening (see Figure 7), which can be used further to calculate the accurate MMD and average molar mass or the PSD and average particle size of the analyzed sample.

## Applications of SEC

The modern SEC is a powerful separation method that, nevertheless, cannot render absolute information on the molar mass or particle size of the

**Figure 8** Schematic representation of a procedure of SEC data treatment.

separated species. The main chromatographic data, the retention volume of the peak, the width and shape of the chromatogram are, however, very precisely measured quantities that, either by means of a calibration procedure and/or through a combination of the SEC separation system with a suitable absolute detector, provide the required information on the molecular characteristics or size of the samples under investigation.

As mentioned in the previous paragraph, the calibration curve constructed by relating an average molar mass to the retention volume of a series of preferentially narrow MMD polymer samples can be used only for the determination of the MMD and average molar masses of an unknown sample of the same chemical composition and structure. The  $[\eta]$  is the intrinsic viscosity determined experimentally. On the other hand, the use of the product  $M[\eta]$ ,

proportional to the hydrodynamic volume of a macromolecular chain in solution, instead of  $M$ , makes the calibration curve independent of the polymer composition and structure in the majority of practical applications of SEC. Consequently, the universal calibration curve constructed with the use of convenient polymer standards can be used for other polymers under condition that the empirical relationships between  $M$  and  $[\eta]$ , called Mark–Houwink equations, for all polymers in question are known. The application of the principle of universal calibration allows also the estimation of the branching of an analyzed unknown polymer due to the fact that the branched polymer chains in solution exhibit lower intrinsic viscosity in comparison with linear chains of the same molar mass. Thus, the use of only an appropriate Mark–Houwink equation for the interpretation of the experimental SEC data of an unknown branched polymer can result in an agreement of the calculated average molar masses and intrinsic viscosities with those measured by independent methods.

This type of measurements can very elegantly be realized online by coupling several detectors at the end of the SEC column such as a concentration detector (refractive index detector, spectrophotometric detector, etc.) and an absolute detector measuring the molar mass or related property of the separated species such as laser light scattering detector or capillary viscometer detector. These modern sophisticated separation systems allow not only the separation of the analyzed species but also their very detailed analysis and characterization as concerns the MMD or PSD, as well as other structural and compositional characteristics of simple polymers, co-polymers, etc. A schematic representation of a procedure of SEC data treatment from an experimental chromatogram to the final MMD or PSD data is shown in **Figure 8**.

Although other separation techniques have become competitive and preferred for particular separations

and detailed analyses of polymers and colloidal particles, such as field-flow fractionation, hydrodynamic chromatography, and various other liquid chromatographies, SEC is still the most extensively applied technique for the molecular characterization of synthetic and natural macromolecules.

## Introduction

For the separation of enantiomers or optical isomers by chromatography, a chiral setup is necessary. This is obtained by the temporary or permanent

formation of diastereoisomers. For the latter approach the sample is derivatized with a chiral reagent, and the separation can then be achieved with a nonchiral chromatographic system; this is the ‘indirect’ method. For the ‘direct’ separation of enantiomers a number of chiral solid stationary phases have been developed and are commercially available, but it is also possible to use a chiral additive to the mobile phase in combination with a

proportional to the hydrodynamic volume of a macromolecular chain in solution, instead of  $M$ , makes the calibration curve independent of the polymer composition and structure in the majority of practical applications of SEC. Consequently, the universal calibration curve constructed with the use of convenient polymer standards can be used for other polymers under condition that the empirical relationships between  $M$  and  $[\eta]$ , called Mark–Houwink equations, for all polymers in question are known. The application of the principle of universal calibration allows also the estimation of the branching of an analyzed unknown polymer due to the fact that the branched polymer chains in solution exhibit lower intrinsic viscosity in comparison with linear chains of the same molar mass. Thus, the use of only an appropriate Mark–Houwink equation for the interpretation of the experimental SEC data of an unknown branched polymer can result in an agreement of the calculated average molar masses and intrinsic viscosities with those measured by independent methods.

This type of measurements can very elegantly be realized online by coupling several detectors at the end of the SEC column such as a concentration detector (refractive index detector, spectrophotometric detector, etc.) and an absolute detector measuring the molar mass or related property of the separated species such as laser light scattering detector or capillary viscometer detector. These modern sophisticated separation systems allow not only the separation of the analyzed species but also their very detailed analysis and characterization as concerns the MMD or PSD, as well as other structural and compositional characteristics of simple polymers, co-polymers, etc. A schematic representation of a procedure of SEC data treatment from an experimental chromatogram to the final MMD or PSD data is shown in **Figure 8**.

Although other separation techniques have become competitive and preferred for particular separations

and detailed analyses of polymers and colloidal particles, such as field-flow fractionation, hydrodynamic chromatography, and various other liquid chromatographies, SEC is still the most extensively applied technique for the molecular characterization of synthetic and natural macromolecules.

## Introduction

For the separation of enantiomers or optical isomers by chromatography, a chiral setup is necessary. This is obtained by the temporary or permanent

formation of diastereoisomers. For the latter approach the sample is derivatized with a chiral reagent, and the separation can then be achieved with a nonchiral chromatographic system; this is the ‘indirect’ method. For the ‘direct’ separation of enantiomers a number of chiral solid stationary phases have been developed and are commercially available, but it is also possible to use a chiral additive to the mobile phase in combination with a

nonchiral stationary phase; a further technique is the use of a chiral liquid stationary phase that is coated on a solid support. All the common liquid chromatography (LC) detectors can be used, but chiroptical devices such as the polarimeter and the circular dichroism spectrometer can also be especially helpful for qualitative analysis. It is possible to obtain circular dichroism spectra online during the elution of the peaks.

## The Analytical Problem

Enantiomers are asymmetric molecules such that one isomer is the mirror image of the other. As long as their environment is symmetrical they have identical physical and chemical properties and they cannot be distinguished. This changes as soon as they interact with asymmetric objects or fields. Such a chiral (from Greek *cheir* for hand) environment is typically found in biological processes because enzymes, receptors, etc., are three-dimensional asymmetric objects. (An important chiral field is polarized light.) Therefore, it is more a rule than an exception that the two forms of enantiomers that interact with a living organism show different actions: leucine has a sweet or bitter taste, amphetamine is a potent or an inactive stimulant of the central nervous system, and permethrin is a toxic or an almost ineffective insecticide. The demand for efficient analytical and preparative methods for enantiodifferentiation is well established. Chromatographic techniques have brought important improvements in both areas.

For all chromatographic enantioselective techniques it is necessary to create a chiral environment. If the method of separation is LC, especially high-performance liquid chromatography, four different techniques are available; ordered in decreasing importance they are given as follows:

1. The use of a chiral solid stationary phase (usually termed chiral stationary phase, CSP).
2. The formation of diastereoisomers by derivatization with a chiral reagent prior to chromatography on a nonchiral separation system.
3. The use of a chiral mobile phase, which is obtained by the addition of a small amount of chiral reagent to the eluent.
4. The use of a chiral liquid stationary phase. The packing of an LC column, e.g., silica, is coated with a film of a liquid, optically pure compound that must not be soluble in the mobile phase used. A possible phase pair is a tartrate derivative in combination with an aqueous buffer eluent. The handling of such liquid-liquid chromatographic systems is not simple, which is why they are not often used, and they are

not discussed further here. They have been replaced by CSPs.

The fact that the separation of enantiomers is possible with chiral chromatographic systems can be explained by the temporary formation of diastereoisomeric adducts or complexes between the analytes and the CSP or chiral liquid stationary phase. To obtain enantiodifferentiation it is necessary that the two forms of the isomer differ in the number of binding points or in their bonding energy. These non-permanent bondings or interactions can be of the dipole-dipole (induced or permanent), hydrogen bonding,  $\pi$ - $\pi$  interaction, or d-orbital (metal complexation) type. Obviously, a separation is possible if one enantiomer is retained by three binding interactions and the other one by only two of them. This principle is shown in **Figure 1** and is known as three-point interaction rule. Although there is no doubt that it is a valid concept, it needs expansion in various respects: the points of interaction must be directly related to the chiral center but in differing directions; both enantiomers can interact at three points but with differing energy at least at one point; or one of the interactions can be repulsive or even neutral and effective only by guiding the sample molecules sterically.

For the characterization of the separation of a pair of enantiomers the separation factor  $\alpha$  is usually used;  $\alpha$  is the ratio of retention factors  $k$ , which are the measure of retention (eqn [1]):

$$\alpha = \frac{k_2}{k_1} = \frac{t_{R2} - t_0}{t_{R1} - t_0} \quad \text{with } k_2 \geq k_1 \quad [1]$$

where  $t_R$  is the retention time of a compound and  $t_0$  the breakthrough time.

The separation factor  $\alpha$  is directly related to thermodynamic parameters, i.e., to the difference in free energy  $\Delta(\Delta G)$ , enthalpy  $\Delta(\Delta H)$ , and entropy  $\Delta(\Delta S)$  of adsorption of the two enantiomers, gas constant  $R$ , and absolute temperature  $T$  (eqn [2]):

$$-RT \ln \alpha = \Delta(\Delta G) = \Delta(\Delta H) - T\Delta(\Delta S) \quad [2]$$

In most cases, the separation of enantiomers on CSPs is controlled by the difference of adsorption enthalpies and  $\alpha$  increases with decreasing temperature. The effects and thus the separation factors are small (which means unfortunately that nonchiral retention is dominating). An  $\alpha$  of 1.05 corresponds to a free energy difference of adsorption of  $120 \text{ J mol}^{-1}$  and a minimum of 8000 theoretical plates is necessary to obtain good resolution (gas constant,  $R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1}$  with  $k_1 = 10$ ; the calculation is performed by means of the chromatographic resolution equation).

**Figure 1** Three representations of the three-point interaction rule for chiral recognition: (A) All molecules involved have tetrahedral structure; one enantiomer can interact with three points because of the fit of AA', BB', CC', whereas with the other no more than a two-point interaction is possible if the molecule is turned suitably; (B) The same principle visualized using hands. Here a three-point interaction is only possible with the *RS* adduct, the *SS* (or *RR*) adduct allows two interactions only; and (C) A model that explains the elution order of *N*-arylsulphinamoyl esters (right) on a dinitrobenzoylamide type CSP (left). It is assumed that four interactions occur (but two of them belong to the same direction, as seen from the chiral center of the sample molecule which is the sulfur atom), three hydrogen bonds and a  $\pi$ - $\pi$  interaction, between the CSP and the more strongly retained enantiomer. In the other enantiomer two groups at the chiral center have changed position and fewer interactions can occur. ((A) and (B) after Meyer VR and Rais M (1989) *Chirality* 1: 167; (C) Reproduced with permission from Caude M, Tambuté A, and Siret L (1991) Chiral stationary phases derived from tyrosine. *Journal of Chromatography* 550: 357.)

## Chiral Stationary Phases

A large number of CSPs have been developed and many of them are commercially available. The most important of them are listed in Table 1. They can be grouped as follows:

1. 'Brush'-type CSPs where small molecules, usually with  $\pi$ -active groups, are bonded to silica.
2. Helical polymers, mainly cellulose and its derivatives.
3. Cavity phases such as cyclodextrins, crown ethers, and macrocyclic compounds.
4. Protein phases.
5. Ligand exchange phases.

A great number of separation problems can be solved by the use of CSPs. They are expensive but can be very effective and simple to use, although the user

needs to discover which type is best suited for a given problem. They were the key that opened the door to contemporary enantioselective chromatography and only subsequently were chiral additives to the mobile phases and the indirect approach (the formation of diastereoisomers) studied more profoundly.

### 'Brush-Type' CSPs

The OH groups of silica can be derivatized by converting them to  $-\text{O}-\text{Si}-\text{O}-\text{R}$  groups where R can be of any type. If R is small and not cross-linked, the new moieties can be considered as bristles fixed to the silica surface. The CSP shown in Figure 1C is of this type; the hatched part at the top of the drawing represents silica. The first broadly used and still very important CSP is the brush-type dinitrobenzoylphenylglycine (DNBPG), shown first in Table 1. After its

inventor, William H. Pirkle, it is often called 'Pirkle-phase', although a more correct name is 'Pirkle I' because it is not the only one of his phases on the market.

The DNBPG phase has a number of features that are typical of almost all of the brush-type CSPs. It has two amide groups that are rigid (planar), and

therefore the whole chiral moiety will prefer a limited (i.e., not an unlimited) number of conformations, which is important for chiral recognition. The amide groups can undergo dipole-dipole interactions as well as hydrogen bonding with suitable sample molecules. The dinitrobenzoyl group is a  $\pi$ -acceptor (the ring has a slightly positive charge) and will

preferentially interact with  $\pi$ -donors such as anilines, phenols, chlorobenzenes, and naphthalenes. This interaction is assumed to be the most important one and there is no practical chance of obtaining a separation of enantiomers that do not bear this type of group. Therefore, nonchiral derivatization is popular: amines and amino acids are converted to naphthamides, alcohols to naphthyl carbamates, and carboxylic acids to anilides. Usually, the derivatization is simple and improves detectability because the groups brought into the molecule have excellent ultraviolet (UV) absorption. The DNBPG phase is relatively cheap and is available in both enantiomeric forms. This can be important for trace analysis, where the small peak should be eluted ahead of the neighboring large peak, or in preparative applications, where the first eluted peak can usually be obtained in pure form whereas the second peak is contaminated by its forerunner.

Other brush-type CSPs are used in a similar manner: dinitrobenzoylleucine, naphthylalanine, naphthylleucine, chrysanthemoylphenylglycine, naphthylethylurea to name but a few (see Table 1). They all have their specificities for certain classes of compounds, although this is sometimes difficult to predict. For an idea of their individual abilities the literature or the brochures provided by the manufacturers may be consulted.

Brush-type CSPs are robust and allow high sample loads. As an example, Figure 2 shows the separation of oxazepam acetate and its hydrolysis product on dinitrobenzoylleucine.

**Figure 2** Separation of the enantiomers of oxazepam acetate and oxazepam on a chiral stationary phase. Column: 4.6 mm  $\times$  25 cm; stationary phase: (*S*)-dinitrobenzoylleucine covalently bonded to 5  $\mu$ m silica; mobile phase, hexane-ethanol-acetonitrile (91.5:5.7:2.8, v/v/v), 2 mL min<sup>-1</sup>; detector, UV 231 nm. Racemic oxazepam 3-acetate was hydrolyzed by human liver microsomes, giving racemic oxazepam. The microsomes strongly preferred the (*R*) enantiomer; after incomplete hydrolysis the remaining oxazepam acetate had a composition of 91.8% (*S*) and 8.2% (*R*) enantiomers. (Reproduced from Yang SK, Liu K, and Güengerich FP (1990) Enantioselective hydrolysis of oxazepam 3-acetate by esterases in human and rat liver microsomes and rat brain S9 fraction. *Chirality* 2: 150.)

of spirobichromene is performed on cellulose tribenzoate; this is not by chance, but helical polymers are suited in an excellent manner for the resolution of enantiomers of 'twisted' molecules (although a vast number of 'flat' compounds can be resolved as well).

### Cavity Phases

Underivatized microcrystalline cellulose is not an effective agent for the LC separation of enantiomers but its derivatives have been shown to be a most interesting and versatile family of CSPs. Cellulose triacetate is available as a bulk material (in this form it is rather cheap) as well as coated on silica. Other derivatives are cellulose tribenzoate (also shown in Table 1), tris(phenylcarbamate), tris(dimethylphenylcarbamate), tris(chlorophenylcarbamate), tris(toluylate), and tricinnamate. They are expensive and perhaps less robust than the brush-type CSPs, but the range of enantiomers that can be separated by them (as a family) is the broadest and most impressive one of all the CSP groups. Their range of application is expanded by poly(triphenylmethacrylate), its derivative where one of the phenyl groups is replaced by a pyridyl moiety, and by amylose derivatives. The retention and separation mechanisms are complex. Figure 5 is presented to demonstrate the possibilities of a circular dichroism detector, but the separation

There are three classes of cyclic chiral selectors in use as CSPs, cyclodextrins, crown ethers, and macrocyclic glycopeptide antibiotics. They can undergo host-guest complexes with small molecules if these can fit into the ring structure; for enantiodifferentiation this fit needs to be stereochemically controlled. Cyclodextrins are oligoglucoses with six, seven, or eight units. Table 1 shows  $\beta$ -cyclodextrin, which is the heptamer and which is used most frequently.  $\alpha$ -Cyclodextrin has six glucose units and  $\gamma$ -cyclodextrin has eight. Glucose itself is chiral and in the cyclodextrin molecule, which in fact is a truncated cone, the superstructure of directed primary (at the smaller rim of the cone) and secondary (at the wider rim) hydroxy groups yields chiral binding points that seem to be essential for enantioselectivity. These

**Figure 3** Separation of citalopram and its demethylated metabolites in a human plasma extract on a vancomycin phase. Column: 4.6 mm  $\times$  15 cm; stationary phase: Chirobiotic V, 5  $\mu$ m; mobile phase: methanol–acetic acid–triethylamine (99.9:0.055:0.06, v/v/v), 1 ml min<sup>-1</sup>; detector: fluorescence 240/296 nm. The structure of the drug is shown; it is used as the racemate. Peaks: 1, alprenolol (internal standard); 2, *R*-(–)-didesmethylcitalopram; 3, *R*-(–)-desmethylcitalopram; 4, *R*-(–)-citalopram; 5, *S*-(+)-citalopram; 6, *S*-(+)-desmethylcitalopram. *S*-(+)-didesmethylcitalopram is not present. (Reproduced with permission from Kosel M, Eap CB, Amey M, and Baumann P (1998) Analysis of the enantiomers of citalopram. *Journal of Chromatography B* 719: 234.)

groups can also be derivatized, e.g., acetylated. Cyclodextrins are used like reversed phases, i.e., with very polar mobile phases. They can separate a wide range of chiral samples, but it is difficult to predict their suitability for a given compound.

Chiral crown ethers of the 18-crown-6 type can resolve amino acids as well as primary amines with close neighborhood of amino function and the center of asymmetry. The interaction occurs between the amino protons and the crown ether oxygens. The groups R and R' of the crown ether need to be large and rigid, e.g., binaphthyls, in order to force the small guest molecules into a well-defined interaction with the host.

The antibiotics vancomycin (shown in Table 1), teicoplanin, and ristocetin A can be bonded to silica, giving a unique class of macrocyclic glycopeptide CSPs. They can be used in the normal-phase mode with a nonpolar eluent as well as in the reversed-phase mode with an aqueous eluent. They show unique selectivity for a large number of analytes. Figure 3 gives an example with the separation of the antidepressant citalopram and its metabolites on a vancomycin CSP.

### Proteins

It is well known in biochemistry that many proteins, especially enzymes and also transport proteins such as albumin, show high enantioselectivities in their

interactions with small chiral molecules. It is possible to bind proteins to silica and to obtain a valuable class of CSPs that are mainly suited for the separation of chiral drugs. Several protein phases are commercially available: albumins,  $\alpha_1$ -acid glycoprotein, ovomucoid, cellobiohydrolase, pepsin, and avidin. They differ in their chromatographic and enantioselective properties, which is to be expected as their biological functions, and their sizes, shapes, or isoelectric points are quite different.

Protein phases are expensive and delicate; their performances (as plate numbers) and capacities are low. For many applications these drawbacks are outweighed by their excellent enantioselectivity.

### Ligand Exchange Phases

Amino acids bonded to silica and loaded with Cu<sup>2+</sup> ions can interact in stereoselective manner with amino acids in aqueous solution. The copper ion forms a complex with both the bound and the sample amino acids. Ligand exchange phases are suited for the separation of amino acids as well as of some  $\beta$ -amino alcohols and similar molecules because these compounds bear two polar functional groups with appropriate spacing. This approach has found limited interest because the column efficiencies are rather low, the detectability of the nonderivatized sample

compounds can be a problem, and the mobile phase needs to contain copper.

## Derivatization with Chiral Reagents to Obtain Diastereoisomers

This is the 'indirect' approach for the chromatographic separation of enantiomers. The reaction of the two forms of an enantiomer with an optically pure chiral reagent gives a mixture of diastereoisomers that are not mirror images of each other and therefore can be separated on a nonchiral, common LC phase. This is shown in Figure 4 where amino acids have been derivatized with *o*-phthalaldehyde and *N*-isobutyl-

L-cysteine and can be resolved on an octadecyl-silica phase. The analyst can choose from a wide range of reagents, among which only the price may sometimes be a problem; in contrast, the stationary phase is cheap. Besides the fact that the sample molecule needs to have a derivatizable functional group, there are several other points needing consideration.

The chiral reagent must be optically pure. Otherwise four reaction products are formed, namely two pairs of enantiomers, and the enantiomers will not be resolved but will influence the analytical result. If the reagent has a purity of 99.5%, the maximum optical purity of the sample that can be determined is 99.0%. The reaction should run quantitatively,

**Figure 4** Separation of amino acid enantiomers on a nonchiral stationary phase after derivatization to diastereoisomers with a chiral reagent. (A) Derivatization scheme. The chiral moiety of the reagent is *N*-isobutyl-L-cysteine, which together with *o*-phthalaldehyde and amino acids forms a fluorescing indole. (B) Amino acid enantiomers found in gelatin hydrolysate. Column: 4.0 mm × 25 cm; stationary phase, Hypersil ODS 5 μm; mobile phase, eluent A, 23 mmol l<sup>-1</sup> sodium acetate pH 6.0; eluent B, methanol–acetonitrile (92.3:7.7 v/v), gradient from 0 to 53.5% B in 75 min, 1 ml min<sup>-1</sup>; detector, fluorescence 230/445 nm. (Reproduced with permission from Brückner H, Wittner R, and Godel H (1991) Fully automated HPLC separation of D,L-amino acids derivatized with OPA together with *N*-isobutyl-cysteine. *Chromatographia* 32: 383.)

without racemization and without giving by-products. The necessary excess of reagent usually needs to be removed prior to injection because otherwise a reagent peak will be found in the chromatogram. Diastereoisomers can have different detector properties (e.g., UV absorptivities) and a calibration graph must be obtained for quantitative analysis.

The functional group to be derivatized should be situated close to the chiral center. It is advantageous to obtain diastereoisomers with a certain rigidity such as amides, carbamates, or ureas. If one can choose and needs to determine small amounts of one enantiomer in the presence of an excess of the other, it is often necessary to use the enantiomeric form of the reagent that elutes the small peak first. (This was not done and was not necessary for the analysis presented in Figure 4.)

For biological samples in particular, the derivatization step can often be coupled to the necessary sample cleaning procedures in an elegant and highly effective manner. By the incorporation of fluorescing or otherwise highly detector-active groups, the detectability of the compound of interest can be improved by several orders of magnitude.

## Chiral Additives to the Mobile Phase

Another approach to creating an asymmetrical environment is the use of a chiral mobile phase where the stationary LC phase is of the usual, nonchiral, type. It is not necessary to use a very expensive chiral solvent and it is sufficient to dissolve rather small amounts of a chiral compound in the eluent. In Figure 5, propafenone, a secondary amine and anti-arrhythmic drug, could be separated into the enantiomers by adding  $3 \times 10^{-3} \text{ mol l}^{-1}$  *N*-benzyloxycarbonylglycyl-L-proline to the mobile phase. This reagent allows multipoint interaction because it has a carboxylic group, which forms an ion pair with propafenone, and a carbamate and amide group that are suitable for hydrogen bonding or dipole-dipole interactions.

The advantages are similar to those of the indirect method: the additive can be chosen from a wide range and in some cases its chirality can be adapted to the separation problem; the stationary phase is cheap. In fact, the reagent does not necessarily need to be optically pure (although it should not be a racemate), but decreasing enantiomeric purity reduces the separation factor. The price of the reagent can be high. The interaction between the chiral selector and the sample can be based on inclusion (e.g., with cyclodextrins), on complexation (e.g., with amino acid-copper additives), on ion pair formation (e.g.,

**Figure 5** Separation of propafenone in plasma by means of a chiral additive to the mobile phase. (A) Structures of propafenone (PFN) and the reagent *N*-benzyloxycarbonylglycyl-L-proline (ZGP). (B) Chromatogram of spiked plasma. Stationary phase, Nucleosil 5 cyano; mobile phase, dichloromethane with  $3 \times 10^{-3} \text{ mol l}^{-1}$  ZGP,  $1.5 \times 10^{-3} \text{ mol l}^{-1}$  triethylamine, and  $250 \mu\text{g ml}^{-1}$  water,  $1 \text{ ml min}^{-1}$ ; detector, UV 300 nm; internal standard (IS), (–)-propranolol. (Reproduced with permission from Prevot M, Tod M, Chalom J, Nicolas P, and Petitjean O (1992) Separation of propafenone enantiomers by LC with a chiral counter ion. *Journal of Chromatography* 605: 33.)

with quinine or the reagent used in Figure 5), or on hydrogen bondings and dipoles (e.g., with amino acid derivatives).

It must be considered that this approach is based on chemical equilibria in solution that may be strongly dependent on temperature, pH, or concentration. It is good practice to investigate the influence

**Figure 6** Separation of a racemic spirobichromene and nonstop circular dichroism (CD) spectral acquisition. The two enantiomeric forms are eluted at 52 and 79 min, respectively, and their CD spectra have two bands of same sign and one band of opposite sign each. In two-dimensional representation the dashed lines correspond to a spectrum (line at 52 min) or to a chromatogram (line at 228 nm). Stationary phase, microcrystalline cellulose tribenzoate; mobile phase, methanol,  $0.7 \text{ mL min}^{-1}$ . (Reproduced from Mannschreck A (1992) Chiroptical detection during LC. *Chirality* 4: 163.)

of these parameters on the ruggedness of the method and to control them very strictly if necessary.

## Chiroptical Detection

Enantioselective chromatographic separation can be supported effectively by chiroptical detection. Unfortunately, progress in this field is slower than in separation techniques, although the need is proven.

Optical rotation and circular dichroism can both be utilized for detection. It may be advantageous to couple the chiroptical device to an ordinary LC detector such as a UV or fluorescence detector. A polarimeter measures the rotation, giving positive and negative signals if a resolved pair of enantiomers is passing through its flow cell. One thereby obtains confirmation that a given chromatographic peak is indeed from a chiral compound, and additionally information about the absolute configuration (in  $+/-$  terms) is obtained. It is not even necessary to have complete chromatographic resolution and it is possible to find chiral compounds that are eluted together with a nonchiral solute.

Circular dichroism, i.e., the difference in absorption of right and left circularly polarized light of the same wavelength, can also be used for detection. Again, the two forms of an enantiomer give a positive and a negative signal as in the polarimeter but the sensitivity can be higher and the range of detectability is extended to lower wavelengths. It is also

possible to obtain circular dichroism spectra with stopped-flow or even true online techniques. This allows positive identification of a compound or gives information about the structure of an unknown. **Figure 6** presents an example of this technique.

The ratio of circular dichroism  $\Delta A$  and absorbance  $A$  is termed the  $g$  factor ( $g = \Delta A/A$ ) and is directly related to the enantiomeric excess of a mixture of enantiomers. It is possible to build a  $g$  detector that gives information on the enantiomeric composition of the eluate at any moment during the chromatogram. This is helpful for fraction collection during the preparative chromatographic separation of enantiomers.

## Affinity Chromatography

**D S Hage**, University of Nebraska, Lincoln, NE, USA

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Affinity chromatography can be defined as a liquid chromatographic method in which a biological agent or biomimetic ligand is used for the selective retention of complementary compounds. This form of liquid chromatography was originally used by Starckenstein in 1910 for the purification of amylase through the use of starch as a solid support. This method continued to slowly develop over the next 50 years. However, it was not until the 1960s that suitable supports like beaded agarose, as developed by Hjerten, became available as well as relatively simple immobilization techniques for these supports. An important advancement in this latter area was a report in 1967 by Axen, Porath, and Ernback in which the cyanogen bromide method for protein and peptide immobilization was first reported. This approach was then used in 1968 by Cuatrecasas, Anfinsen, and Wilchek to purify enzymes through the use of immobilized enzyme inhibitors. It was also at this time that the term ‘affinity chromatography’ was proposed to describe this technique.

Affinity chromatography is relatively simple to perform and is a powerful tool for the separation of biological macromolecules. The high selectivity of this approach often allows single-step purification strategies to be developed, even when working with dilute and highly complex mixtures. This simplicity and the variety of ligands that can be used with this approach have made it an important tool in process-scale separations. However, modern affinity chromatography also plays an important role in the

analysis and study of biological systems. For instance, most forms of chiral liquid chromatography, such as those using immobilized cyclodextrins or serum proteins, can be considered a subcategory of affinity chromatography.

### Basic Principles of Affinity Chromatography

#### The Process

Affinity chromatography relies on the specific recognition that occurs between many biological species, such as the binding of an antibody with an antibody or hormone with its receptor. These interactions are used in affinity chromatography by permanently bonding (or ‘immobilizing’) onto a solid support an appropriate binding agent. This immobilized agent is known as the affinity ligand and represents the stationary phase for this method. Once the affinity ligand and its support have been placed within a column, this column can be used to retain any substance that will form a strong but reversible complex with the ligand. The optimum association constant ( $K_a$ ) for such a system in purification work is generally  $10^4$ – $10^8$  l mol<sup>-1</sup>. However, stronger and weaker interactions can be used in analytical applications of affinity columns.

The most common format employed with affinity columns is given in **Figure 1**. In this scheme, a solution containing the target of interest is passed through a column containing an immobilized ligand capable of binding the target. This is performed in the presence of an application buffer that allows such binding to occur. Since this interaction is usually selective in nature, the ligand will recognize and retain the target while allowing other compounds in

### Introduction

Affinity chromatography can be defined as a liquid chromatographic method in which a biological agent or biomimetic ligand is used for the selective retention of complementary compounds. This form of liquid chromatography was originally used by Starckenstein in 1910 for the purification of amylase through the use of starch as a solid support. This method continued to slowly develop over the next 50 years. However, it was not until the 1960s that suitable supports like beaded agarose, as developed by Hjerten, became available as well as relatively simple immobilization techniques for these supports. An important advancement in this latter area was a report in 1967 by Axen, Porath, and Ernback in which the cyanogen bromide method for protein and peptide immobilization was first reported. This approach was then used in 1968 by Cuatrecasas, Anfinsen, and Wilchek to purify enzymes through the use of immobilized enzyme inhibitors. It was also at this time that the term ‘affinity chromatography’ was proposed to describe this technique.

Affinity chromatography is relatively simple to perform and is a powerful tool for the separation of biological macromolecules. The high selectivity of this approach often allows single-step purification strategies to be developed, even when working with dilute and highly complex mixtures. This simplicity and the variety of ligands that can be used with this approach have made it an important tool in process-scale separations. However, modern affinity chromatography also plays an important role in the

analysis and study of biological systems. For instance, most forms of chiral liquid chromatography, such as those using immobilized cyclodextrins or serum proteins, can be considered a subcategory of affinity chromatography.

### Basic Principles of Affinity Chromatography

#### The Process

Affinity chromatography relies on the specific recognition that occurs between many biological species, such as the binding of an antibody with an antibody or hormone with its receptor. These interactions are used in affinity chromatography by permanently bonding (or ‘immobilizing’) onto a solid support an appropriate binding agent. This immobilized agent is known as the affinity ligand and represents the stationary phase for this method. Once the affinity ligand and its support have been placed within a column, this column can be used to retain any substance that will form a strong but reversible complex with the ligand. The optimum association constant ( $K_a$ ) for such a system in purification work is generally  $10^4$ – $10^8$  l mol<sup>-1</sup>. However, stronger and weaker interactions can be used in analytical applications of affinity columns.

The most common format employed with affinity columns is given in **Figure 1**. In this scheme, a solution containing the target of interest is passed through a column containing an immobilized ligand capable of binding the target. This is performed in the presence of an application buffer that allows such binding to occur. Since this interaction is usually selective in nature, the ligand will recognize and retain the target while allowing other compounds in

**Figure 1** Typical separation scheme for affinity chromatography, showing the steps for sample application, column washing, analyte/target elution, and column regeneration.

the sample to pass through the column in the non-retained peak. However, due to the strong binding between the target and ligand, the target is held within the column until the mobile phase or chromatographic conditions are varied. This is often accomplished by later passing an elution buffer through the column. As the target elutes from the column, it is captured for further use or monitored by an online detector. The column is then cleaned, allowed to regenerate in the application buffer, and used for the next sample. As this scheme suggests, there are several factors to consider in the design of an affinity separation. These include the ligand, support material, immobilization method, and application or elution conditions.

### The Affinity Ligand

Examples of ligands used in affinity chromatography are given in **Table 1**. The ligand can be a naturally occurring biomolecule, an engineered macromolecule, or synthetic substance. Examples of naturally occurring ligands employed in this technique include enzyme inhibitors, hormones, lectins, antibodies, and nucleic acids, which are used to bind enzymes,

**Table 1** Affinity ligands and their target compounds

Type of affinity ligand	Typical targets
<i>Biological agents</i>	
Lectins	Glycoproteins, cells
Carbohydrates	Lectins and other carbohydrate-binding proteins
Nucleic acids	Exonucleases, endonucleases, and polymerases
Cofactors, substrates, and inhibitors	Enzymes
Protein A and protein G	Antibodies
Hormones and drugs	Receptors
Antibodies	Antigens
<i>Nonbiological ligands</i>	
Metal-ion chelates	Proteins and peptides that bind metal ions
Synthetic dyes	Enzymes and various nucleotide-binding proteins

receptors, polysaccharides, antigens, and nucleic acid-binding proteins, respectively. Nonbiological ligands that have been used in affinity columns include immobilized chelates of metal ions (e.g.,  $\text{Ni}^{2+}$ ), reactive dyes, and molecularly imprinted polymers.

As shown in **Table 1**, many ligands are biological macromolecules. These can take part in several types of interactions as they bind to their targets, including electrostatic forces, hydrogen bonding, dipole–dipole interactions, and van der Waals forces. The specific recognition between the ligand and target is due to a combination of these interactions as well as the fit between these species. This is the source of the high affinity seen for many ligands in affinity columns.

All affinity ligands can be grouped into one of two categories: group-specific ligands and high-specificity ligands. High-specificity ligands are generally based on biological agents. A common example is the binding of an antibody with the foreign substance (or antigen) to which the antibody was initially raised. These ligands tend to have relatively large association constants and generally require a step gradient for elution. Group-specific (or general) ligands are agents that bind to a class of related molecules. These recognize a common structural feature on their targets and can be either biological or nonbiological in origin. Examples include protein A, protein G, lectins, boronates, dyes, and immobilized metal-ion chelates. Depending on their affinity, group-specific ligands may require either step elution (e.g., lectins, protein A, and protein G) or may allow the use of isocratic elution (e.g., as occurs in some applications of boronates and immobilized metal-ion chelates).

There are several terms used to classify affinity methods based on the ligands they employ. For instance, bioaffinity chromatography (or biospecific

adsorption) is a term used to describe any affinity method that has a biological molecule as the ligand. This category can be further subdivided into other techniques. As an example, the use of antibodies (or immunoglobulins) as affinity ligands is often referred to as immunoaffinity chromatography, and the use of lectins as ligands is commonly known as lectin affinity chromatography. Other classifications based on the type of ligand include (1) dye-ligand or biomimetic affinity chromatography, which generally uses an immobilized synthetic dye; (2) immobilized metal-ion affinity chromatography, in which the ligand is a metal ion complexed with an immobilized chelating agent; and (3) boronate affinity chromatography, in which boronic acid or one of its derivatives is utilized as the ligand.

### The Support

The support is the material or matrix that holds the ligand within the affinity column. Table 2 shows various materials that have been employed for this purpose. Ideally, this support should have low non-specific binding for sample components but should be easy to modify for ligand attachment. This material should also be stable under the flow rate, pressure, and solvent conditions to be employed in the analysis or purification of samples. In addition, the support should be readily available and simple to use in method development.

Depending on what type of support material is being used, affinity chromatography can be characterized as either a low- or high-performance technique. In low-performance (or column) affinity chromatography, the support is usually a large

diameter, nonrigid gel. Many of the carbohydrate-based supports and synthetic organic materials listed in Table 2 fall within this category. The low back-pressure and reasonable cost of these supports makes them useful for large-scale processing and small-scale preparative work. However, they also tend to have slow mass transfer and limited stability at high flow rates and pressures. These factors limit the usefulness of these supports in analytical applications, where both rapid and efficient separations are often desired. In high-performance affinity chromatography, the supports generally consist of small, rigid particles capable of withstanding the flow rates and/or pressures characteristic of high-performance liquid chromatography (HPLC). Examples of supports suitable for such work include modified silica or glass and hydroxylated polystyrene media. The mechanical stability and efficiency of these supports allows them to be used with standard HPLC equipment. This results in a separation with good speed and precision, making it useful in analytical applications.

One desirable characteristic for the support is that it should allow easy access of the target to the ligand. For a porous material, this requires that the support have pores at least several-fold larger than the target. However, the use of a support with large pores will also have a low surface area per unit volume, which will limit the number of ligands that can be attached to the surface. In process-scale work another requirement for the support is that it should be possible to routinely sanitize this without causing damage. This generally requires that the support be resistant to reagents such as concentrated sodium hydroxide or 8 mol l<sup>-1</sup> urea.

### Immobilization Methods

The third item to consider in the development of an affinity technique is the way in which the ligand is attached to the solid support, or the immobilization method. There are many ways immobilization can be accomplished. These approaches include simple adsorption to a solid support, bioselective adsorption to a secondary ligand (e.g., the noncovalent binding of antibodies to immobilized protein A), entrapment, imprinting, and covalent attachment.

There are several criteria that should ideally be met for the immobilization method. First, this approach must allow the affinity ligand to be coupled to the support without significantly affecting its binding properties. Second, this method must allow the immobilized ligand to still be accessible to its target. In addition, the immobilization method should not introduce any groups to the support that can give rise to nonspecific binding. Fourth, the amount of ligand

coupled to the support should be optimal for binding to the target and the ligand should be immobilized in a manner that prevents the loss of ligand over time.

Covalent attachment is the most common approach used for ligand immobilization. Some techniques available for this are given in Table 3. For a protein or peptide this generally involves coupling the ligand through amine, carboxylic acid, or sulfhydryl residues present in its structure. Immobilization of a ligand through other functional sites (e.g., aldehyde groups produced by carbohydrate oxidation) is also possible.

### Application and Elution Conditions

The final set of items to consider in the use of affinity chromatography is the selection of application and elution conditions. Most application buffers in affinity chromatography are solvents that mimic the pH, ionic strength, and polarity experienced by the target and ligand in their natural environment. These conditions generally allow for optimum binding between the target and ligand. Any cofactors or metal ions required for solute–ligand binding should also be present in this solvent. In addition, surfactants and blocking agents may be added to the buffer to prevent nonspecific retention on the support or affinity ligand.

The elution buffer can be either a solvent that produces weak binding or one that decreases the extent of this binding by using a competing agent that displaces the target from the column. These two approaches are known as nonspecific elution and biospecific elution, respectively. Biospecific elution is the gentler of these two methods since it is carried out under essentially the same solvent conditions as used for sample application. This makes this approach attractive for purification work, where a high recovery of active target is desired.

In nonspecific elution, a change in column conditions is used to weaken the interactions between retained compounds and the ligand. This can be accomplished by changing the pH, ionic strength, or polarity of the mobile phase. The addition of denaturing or chaotropic agents to the mobile phase can also be employed. This alters the interactions of the target with the ligand, leading to lower retention. Nonspecific elution tends to be much faster than biospecific elution in removing compounds from affinity columns. This results in sharper peaks and lower limits of detection, making nonspecific elution common in analytical applications of affinity chromatography. This method can also be used in purifying solutes, but there is a greater risk of target denaturation with this approach than there is with biospecific elution. Furthermore, care must be taken to avoid using conditions that may harm the support or result in an irreversible loss of ligand activity.

## Applications of Affinity Chromatography

### Preparative Applications

The earliest use of affinity chromatography and its most popular application is in the purification of proteins and other biological agents. The use of this method in enzyme purification is particularly important, with hundreds to thousands of applications having been reported in this field alone. Ligands used for this purpose include enzyme inhibitors, coenzymes, substrates, and cofactors. For instance, nucleotide mono-, di-, and triphosphates can be used for the purification of various kinases, NAD has been used to isolate dehydrogenases, and RNA or DNA has been used for the preparation of polymerases and nucleases.

Antibodies have also been popular ligands for the purification of biological compounds. There are now thousands of examples of immunoaffinity methods that have been developed for the isolation of hormones, peptides, enzymes, recombinant proteins, receptors, viruses, and subcellular components. In

**Figure 2** Structure of Cibacron Blue 3G-A, a stationary phase often used in dye-ligand affinity chromatography.

addition, immobilized antigens are frequently used to isolate specific types of antibodies. A more general purification scheme for antibodies can be obtained by using antibody-binding proteins like protein A and protein G. These latter ligands have the ability to bind to the constant region of many types of immunoglobulins. Both protein A and protein G have their strongest binding to immunoglobulins at or near neutral pH but readily dissociate from these when placed into a lower pH buffer.

Dye-ligand affinity chromatography is often used in large-scale protein and enzyme purification, with over 500 such compounds having been isolated by this technique. In this method, an immobilized synthetic dye is used that binds to the active site of a target by mimicking the structure of its substrate or co-factor. The most common dye used for this purpose is Cibacron Blue 3G-A (see **Figure 2**). Other dyes used include Procion Blue MX-3G or MX-R, Procion Red HE-3B, Thymol Blue, and Phenol Red. Although these ligands were originally discovered on a trial and error basis, recent work in the area of biomimetic affinity chromatography has used computer modeling and three-dimensional protein structures to develop dyes that compliment the binding pockets of specific target proteins.

### Analytical Applications

Although affinity chromatography was originally created as a preparative method, the past few decades have seen this method also become an important tool in analytical applications. **Table 4** summarizes some strategies that can be employed in these analyses and gives examples of representative applications. The simplest format for using affinity chromatography in analysis involves the traditional step gradient mode, as shown in **Figure 1**. The advantages of using this approach in analytical applications, particularly when performed by HPLC, include its speed, relative simplicity, and good precision.

**Table 4** Analytical applications of affinity chromatography<sup>a</sup>

General application	Examples of analytes
Direct detection	Anti-idiotypic antibodies, antithrombin III, bovine growth hormone, fibrinogen, fungal carbohydrate antigens, glucose tetrasaccharide, glutamine synthetase, granulocyte colony stimulating factor, group A-active oligosaccharides, human serum albumin, immunoglobulin G, immunoglobulin E, interferon, interleukin-2, lymphocyte receptors, $\beta_2$ -microglobulin, tissue-type plasminogen activator, transferrin
Offline affinity extraction	Aflatoxin, albuterol, benzodiazepines, cytokinins, fumonisin, human chorionic gonadotropin, ivermectin and avermectin, nortestosterone, ochratoxin A, oxytocin, phenylurea herbicides, sendai virus protein, trenbolone, triazine herbicides
Online affinity extraction	Aflatoxin M1, $\beta$ -agonists, $\alpha_1$ -antitrypsin, atrazine, atrazine metabolites, benzylpenicilloyl-peptides, bovine serum albumin, carbendazim, carbofuran, chloramphenicol, clenbuterol, cortisol, dexamethasone, diethylstilbestrol, digoxin, estrogens, hemoglobin, human epidermal growth factor, human growth hormone variants interferon $\alpha$ -2, LSD, lysozyme variants
Chromatographic immunoassays	Adrenocorticotrophic hormone, $\alpha$ -amylase, atrazine/triazines, 2,4-dinitrophenyl lysine, human chorionic gonadotropin, human serum albumin, immunoglobulin G, isoproturon, parathyroid hormone, testosterone, theophylline, thyroid stimulating hormone, thyroxine, transferrin, transferrin, trinitrotoluene

<sup>a</sup>The information in this table is based on data provided in Hage (1998).

Affinity extraction is another approach that can be used for solute detection. In this method, an affinity column is used for the removal of a specific solute or group of solutes from a sample prior to their determination by a second method. This employs the same operating scheme as shown in **Figure 1**, but now involves combining the affinity column either offline or online with some other method for the actual quantitation of analytes. This often involves the use of antibodies as ligands, but other binding agents can also be employed.

Offline extraction is the easiest and most common way for combining affinity columns with other analytical techniques. This typically involves the use of antibodies that are immobilized and packed into a disposable syringe or solid-phase extraction cartridge. After conditioning the affinity column with the necessary application buffer or conditioning solvents,

the sample is applied and undesired sample components are washed away. An elution buffer is then applied and the retained target is collected. If desired, the collected fraction can be analyzed directly or first dried down and reconstituted in a solvent that is more compatible with the method to be used for quantitation.

Online affinity extraction can also be used. A typical scheme for performing online immunoextraction with reversed-phase liquid chromatography (RPLC) is shown in **Figure 3**. This involves injecting the sample onto the immunoextraction column, with this column later being switched online with a RPLC column. An elution buffer is then applied to dissociate any retained analyte, which will be captured and reconcentrated at the head of the RPLC column. After all solutes have left the immunoaffinity column, this column is switched back offline and regenerated by passing through the initial application buffer. Meanwhile, the RPLC column is developed with either an isocratic or gradient elution scheme that uses a mobile phase with increased organic modifier content. As the solutes elute through the RPLC column, they are monitored and quantitated through the use of an online detector.

A third way in which affinity chromatography has been used in analytical applications has been in the area of chromatographic, or flow-injection, immunoassays. This method is used in determining trace analytes that do not directly produce a readily detectable signal. The competitive binding assay is the most common format used in performing such an assay. This is generally accomplished by mixing the sample with a fixed amount of a labeled analyte analog (i.e., the 'label') and simultaneously or sequentially injecting these onto an immunoaffinity column that contains a limiting amount of antibody.

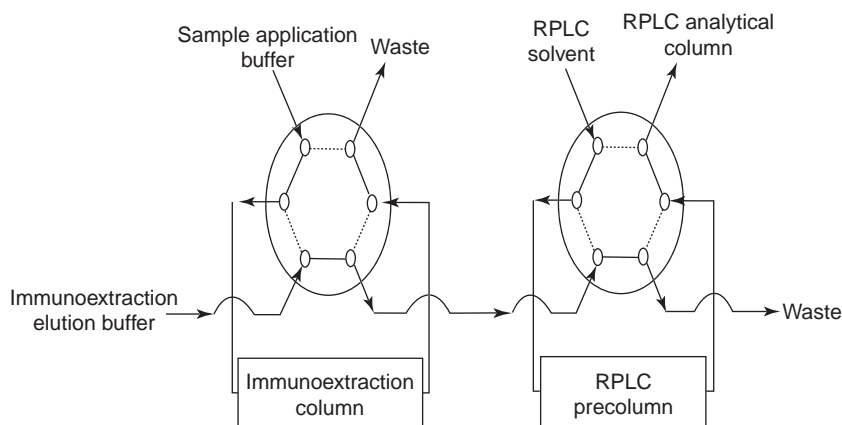

Immunometric assays have also been performed on chromatographic systems. For instance, in a sandwich immunoassay, two different types of antibodies are used (see **Figure 4**). The first of these two antibodies is attached to a solid-phase support and used to extract the analyte from samples. The second antibody contains an easily measured tag and serves to place a label on the analyte, thus allowing it to be quantitated.

### Biophysical Applications

Besides its use in separating and quantitating sample components, affinity chromatography can also be employed as a tool for studying solute–ligand interactions. This approach is called analytical, or quantitative, affinity chromatography. Using this technique, information can be obtained regarding

**Figure 4** Detection of a trace hormone (parathyrin) in human plasma by a chromatographic sandwich immunoassay. The results in (A) show the injection spikes and nonretained fractions for four sequential injections of human plasma samples with increasing parathyrin levels. The results in (B) show the response due to the retained parathyrin. This plot was obtained from Hage and Kao (1991).

**Figure 3** A general scheme for interfacing an immunoextraction column with reversed-phase liquid chromatography (RPLC). The two circles represent six-port switching valves, with the solid and dashed lines showing the flow of sample and solvents in each of the two positions. The operation of this system is described in the text.

**Figure 5** An example of a zonal elution experiment, in which small injections of L-tryptophan are made on to an immobilized human serum albumin column in the presence of increasing amounts of phenytoin in the mobile phase.

the equilibrium and rate constants for biological interactions, as well as the number and types of sites involved in these interactions.

Information on the equilibrium constants for a solute–ligand system can be acquired by using the methods of zonal elution or frontal analysis. Zonal elution involves the injection of a small amount of solute onto an affinity column in the presence of a mobile phase that contains a known concentration of competing agent. The equilibrium constants for the ligand with the solute (and competing agent) can then be obtained by examining how the solute's retention changes as the competing agent's concentration is varied (see **Figure 5**). This method has been used to examine a number of biological systems, such as enzyme–inhibitor binding, protein–protein interactions, and drug–protein binding. Frontal analysis is used in a similar manner but is performed by continuously applying a known concentration of solute to the affinity column. The moles of analyte required to reach the mean point of the resulting breakthrough curve is then measured and used to determine the equilibrium constant for solute–ligand binding.

Information on the kinetics of solute–ligand interactions can also be obtained using affinity chromatography. A number of methods have been developed for this, including techniques based on band-broadening measurements, the split-peak effect, and peak decay analysis. These methods are generally more difficult to perform than equilibrium constant measurements but represent a powerful means for examining the rates of biological interactions. Systems studied by these techniques have

included the binding of lectins with sugars, protein A, or protein G with immunoglobulins, antibodies with antigens, and drugs with serum proteins. The recent creation of commercial sensors for biointeraction studies is one result of such work.

## Multidimensional

**F Hernández and J V Sancho**, University Jaume I, Castellon, Spain

### Introduction

Multidimensional chromatography is a very attractive technique for the analysis of complex mixtures where a mono-dimensional separation cannot be sufficient to resolve all the components of interest. Obvious advantages are the higher peak capacity and resolution offered by these systems. Typically, one part of the chromatogram from the first column is transferred to another column via a suitable interface.

Multidimensional liquid chromatography (MDLC), also known as coupled-column liquid chromatography (LC–LC) or column-switching chromatography, is a particular case of multidimensional chromatography. It can be performed either in offline or online mode. In offline operation, the fractions eluted from the primary column are collected manually or by a fraction collector and then reinjected (either with or without preconcentration) into a second column. This approach has the advantage of being simple, does not need any switching valve, and the mobile phases used in each column need not to be mutually compatible. However, offline procedures usually are laborious and time consuming and the recovery is often low.

Online techniques have the advantage of automation by using pneumatic or electronically controlled valves, which switch the column effluent directly from the primary column into the secondary column. Automation improves reliability and sample throughput and shortens analysis time, as well as minimizes sample loss. Online techniques are commonly preferred although they are not always

feasible from an operational point of view, mainly by limitations in the compatibility of mobile phases.

The term MDLC usually refers to the systems involving different separation modes (i.e., varying the nature of the stationary phase), and because of this reason some authors use the concept of heteromodal LC–LC. Obviously, when orthogonal separation mechanisms are used, the resolving power is significantly increased in relation to mono-dimensional LC. However, if the mechanisms involved lead to an inversion of elution order from the first to the second column, the separation achieved with the whole system can be substantially decreased. Thus, although column selectivity is critical in MDLC, coupling dissimilar stationary phases do not always ensure an orthogonal separation. Tuning operation parameters, such as mobile phase strength, temperature, or buffer strength, is also critical in MDLC. Among the experimental parameters, mobile-phase strength is the most significant one influencing the separation and is the easiest to tune.

In homomodal LC–LC, the chromatographic improvement occurs by switching columns of similar selectivity. This approach is not a genuine multidimensional chromatography but some authors consider it as MDLC. The objective is to improve the analytical methodology pursuing, generally, the concentration of the sample components (sample enrichment) or to shorten the analysis time.

Sample enrichment is one of the most frequent applications of MDLC. These methods are based on the possibility that analytes are retained as a narrow band on the top of the first column when a large volume of sample is pumped. Therefore, the separation power of the first column is not critical, and typically short precolumns or small cartridges are employed. This allows the use of relatively high flow-rates during the sample enrichment step keeping

### Introduction

Multidimensional chromatography is a very attractive technique for the analysis of complex mixtures where a mono-dimensional separation cannot be sufficient to resolve all the components of interest. Obvious advantages are the higher peak capacity and resolution offered by these systems. Typically, one part of the chromatogram from the first column is transferred to another column via a suitable interface.

Multidimensional liquid chromatography (MDLC), also known as coupled-column liquid chromatography (LC–LC) or column-switching chromatography, is a particular case of multidimensional chromatography. It can be performed either in offline or online mode. In offline operation, the fractions eluted from the primary column are collected manually or by a fraction collector and then reinjected (either with or without preconcentration) into a second column. This approach has the advantage of being simple, does not need any switching valve, and the mobile phases used in each column need not to be mutually compatible. However, offline procedures usually are laborious and time consuming and the recovery is often low.

Online techniques have the advantage of automation by using pneumatic or electronically controlled valves, which switch the column effluent directly from the primary column into the secondary column. Automation improves reliability and sample throughput and shortens analysis time, as well as minimizes sample loss. Online techniques are commonly preferred although they are not always

feasible from an operational point of view, mainly by limitations in the compatibility of mobile phases.

The term MDLC usually refers to the systems involving different separation modes (i.e., varying the nature of the stationary phase), and because of this reason some authors use the concept of heteromodal LC–LC. Obviously, when orthogonal separation mechanisms are used, the resolving power is significantly increased in relation to mono-dimensional LC. However, if the mechanisms involved lead to an inversion of elution order from the first to the second column, the separation achieved with the whole system can be substantially decreased. Thus, although column selectivity is critical in MDLC, coupling dissimilar stationary phases do not always ensure an orthogonal separation. Tuning operation parameters, such as mobile phase strength, temperature, or buffer strength, is also critical in MDLC. Among the experimental parameters, mobile-phase strength is the most significant one influencing the separation and is the easiest to tune.

In homomodal LC–LC, the chromatographic improvement occurs by switching columns of similar selectivity. This approach is not a genuine multidimensional chromatography but some authors consider it as MDLC. The objective is to improve the analytical methodology pursuing, generally, the concentration of the sample components (sample enrichment) or to shorten the analysis time.

Sample enrichment is one of the most frequent applications of MDLC. These methods are based on the possibility that analytes are retained as a narrow band on the top of the first column when a large volume of sample is pumped. Therefore, the separation power of the first column is not critical, and typically short precolumns or small cartridges are employed. This allows the use of relatively high flow-rates during the sample enrichment step keeping

reasonable retention capacity. As the main objective is the extraction/preconcentration of analytes, the term online solid-phase extraction (SPE) is often used leading to a SPE–LC coupling. Obviously, some cleanup can also be obtained during this step depending on the type of stationary phase used in the preconcentration cartridge.

LC–LC coupling using two full-size separation columns provides a greatly enhanced peak capacity in relation to one-dimensional techniques. The LC–LC separation can be used in either profiling or target mode. In the first case, the aim is to separate all single components from a complex mixture, in such a way that every fraction from the first column is transferred to the second column. However, the purpose of LC–LC in the target mode is to isolate a specific narrow fraction containing the analyte(s) and to transfer it to the second column after performing an efficient cleanup. The fraction of interest may be formed by early-eluting analytes (front-cut), analytes eluting in the middle of the chromatographic effluent (heart-cut) or late-eluting analytes (end-cut).

This article focuses on these two coupled systems, SPE–LC and LC–LC, considering either homomodal or heteromodal approaches. The main characteristics of these techniques are summarized in **Table 1** and will be discussed in more detail in the subsequent sections.

## SPE–LC Coupling

Online coupling of SPE with LC followed by various modes of detection represents a fast, modern, and

suitable approach for trace analysis. Important advantages are the increase in sensitivity and automation, as well as the lower risks of sample contamination or analyte losses by evaporation. In contrast to LC–LC, no continuous elution occurs in SPE–LC during the first dimension. Ideally, the analytes are fully retained on the SPE phase during the sorption and washing steps, and subsequently, quickly and completely desorbed in a small volume during the elution step. The main difference in relation to the offline approach is the desorption step, since the trapped compounds are eluted directly from the first to the second column by a suitable mobile phase that also acts on the chromatographic separation. The analysis of the complete sample allows the dramatic reduction of the sample volume, in contrast to offline SPE where only an aliquot of the extract is injected into the chromatographic system. Online SPE–LC is a robust technique to be applied in different fields, due to the good compatibility of the LC aqueous mobile phases with the SPE of biological or environmental samples, for example, which are mainly aqueous in nature.

## SPE Sorbents

Typically, trace enrichment has been applied to relatively nonpolar analytes present in aqueous solutions by using small reversed-phase precolumns as C-1 (normally, C<sub>18</sub> silicas). However, other approaches are nowadays applied, mainly due to the development of new sorbents to be used as stationary phases in C-1.

**Table 1** Main characteristics of MDLC techniques: SPE–LC versus LC–LC

<i>Item/issue</i>	<i>SPE–LC</i>	<i>LC–LC</i>
General approach	The whole sample is preconcentrated in a short column/cartridge (C-1) and backflush/forwardflush transferred to the analytical column (C-2)	Target mode where only the fraction containing the analytes is forwardflush transferred from the first column (C-1) to the second analytical column (C-2)
Main objectives	Preconcentration	Selectivity improvement
Advantages	Automation Sensitivity improvement Sample treatment reduction	Automated cleanup Sensitivity improvement by large volume injection (LVI) Sample treatment simplification
Critical/weak points	Retention/preconcentration of interferents Breakthrough volume	Stability/robustness of C-1 Periodical checking of coupling conditions (cleanup and transfer times)
Main application fields	Environment (organic pollutants in water)  Biomedical (drugs and related compounds in biological fluids)	Environment (target analysis of single or a few compounds in complex analyte/matrix combinations) Biomedical (drugs and related compounds, and endogenous compounds in biological fluids)
Trends and developments	Use of more selective retention mechanisms in the preconcentration column (immunosorbents, restricted access media, molecularly imprinted polymers, etc.) Hyphenation to mass spectrometry (MS and MS <sup>n</sup> )	Comprehensive LC–LC applied to the entire profiling of proteins and peptide mixtures (proteomics)  Hyphenation with mass spectrometry (MS and MS <sup>n</sup> )

The extraction of polar analytes in environmental water has been partly solved by the introduction of carbon-based sorbents (e.g., graphitized carbon blacks) and highly cross-linked styrene-divinyl benzene copolymers, and a new generation of polymers (Oasis, Absolut Nexus, etc.) has been designed to extract a wide spectrum of analytes (including hydrophilic, lipophilic, acidic, basic, and neutral). Ion-pair and ion-exchange sorbents allow the extraction of ionic or ionizable analytes. Cation exchangers include weak carboxylic acid and strong aromatic (or nonaromatic) sulfonic acid groups, and anion exchangers are normally made of primary and secondary amino groups (weak) or quaternary amine forms (strong).

Today, there is strong interest in the development of online sample treatment techniques that allow the handling of untreated biological samples. Thus, in online SPE-LC, deproteinization of plasma and serum is required before extraction, especially if the same cartridge is used for repeated analysis. For this purpose, restricted-access materials (RAMs) have been developed, which combine size-exclusion and reversed phase mechanisms, allowing extraction and cleanup of samples in the same step. RAMs have become quite popular for the direct injection of biological fluids, since they prevent the access of matrix components (e.g., proteins) while retaining the analytes in the interior of the sorbent.

There is a considerable interest in using highly selective SPE sorbents that allow extraction, cleanup, and preconcentration in a single step. As a consequence, new selective sorbents have emerged in recent years that are based upon molecular recognition. Immunoaffinity sorbents use immobilized antibodies as packing material and allow a high degree of molecular selectivity. Immunoaffinity SPE-LC in combination with mass spectrometry (MS) or tandem MS is a powerful approach for the determination of organic analytes in biological fluids and offers the very high selectivity required when analytes have to be determined/confirmed at the trace levels in complex matrices.

Recently, molecular imprinted polymers (MIPs) have gained attention as new selective sorbents for chromatography. The cavities in the polymer selectively recognize and bind a specific compound in a similar way as immunoaffinity sorbents, but can be tailor-made. They have the advantages of being prepared more rapidly and easily, and to be stable at high temperatures in large pH ranges. However, most current MIPs require the analyte to be dissolved in nonprotic organic solvents, limiting their use in online SPE of aqueous samples.

## Experimental Setup and Method Development

Online SPE-LC can be easily automated by using commercially available devices as Prospekt (from Spark Holland) or OSP-2 (Merck), which have the capability to switch to a fresh disposable precolumn for every sample. These systems improve the productivity since the next sample is automatically prepared while the previous sample is being analyzed.

The size of the precolumn is of great importance since the profile of the extracted species transferred from the precolumn to the analytical column should be as narrow as possible at the beginning of the separation in order to avoid band broadening. Dimensions of the precolumn should be adapted to those of the analytical column, and are typically 2–15 mm long  $\times$  1–4.6 mm ID for 50–250 mm long analytical columns. Dimensions can be slightly increased without band broadening if an appropriate mobile phase gradient is used.

Desorption of analytes from the precolumn (C-1) and subsequent loading on the analytical column (C-2) can be carried out either in the back-flush or forward-flush modes. The back-flush mode provides better peak shape, but it may lead to precolumn packing disturbances, as well as clogging of the analytical column when real samples are analyzed. Forward desorption allows the precolumns to also act as guard columns; however, depending on the dimension and particle size, this mode can provide additional band broadening of analyte. Both desorption modes are used in practice.

In SPE-LC method development, several parameters have to be optimized. Most effort is directed toward the optimization of the SPE step. Obviously, coupling with LC and experimental conditions for the correct chromatographic separation in the second (analytical) column have to be also optimized. The main parameters involved in the SPE process are: type and amount of sorbent, the sample volume that can be applied without losses of analytes, the composition and volume of the washing solution, and the composition and volume of the elution (desorption) solution. A helpful parameter to characterize the usefulness of a given precolumn is the breakthrough volume, which represents the maximum sample volume that can be loaded into the precolumn with a theoretical 100% recovery (the ratio between the amount of analyte extracted and the amount applied).

As an example, **Figure 1** shows SPE-LC chromatograms for a water sample containing several herbicides, obtained under different experimental conditions (volume of sample passed throughout the

**Figure 1** SPE–LC chromatograms for HPLC water spiked with different herbicides: (1) bromacil, (2) metabenzthiazuron, (3) chlortoluron, (4) diuron, (5) linuron, and (6) chloroxuron. (A) 50 ml sample spiked at  $0.2 \mu\text{g l}^{-1}$  passed throughout a  $\text{C}_{18}$  precolumn ( $30 \times 4 \text{ mm}$ ); (B) 100 ml sample spiked at  $0.1 \mu\text{g l}^{-1}$  passed throughout a  $\text{C}_{18}$  precolumn ( $30 \times 4 \text{ mm}$ ); (C) 50 ml sample spiked at  $0.2 \mu\text{g l}^{-1}$  passed throughout a PRP-1 precolumn ( $10 \times 2 \text{ mm}$ ); and (D) 100 ml sample spiked at  $0.1 \mu\text{g l}^{-1}$  passed throughout a PRP-1 precolumn ( $10 \times 2 \text{ mm}$ ). In all cases, C-2 is a  $\text{C}_{18}$  column ( $125 \times 4 \text{ mm}$ ). Mobile phase: acetonitrile–water gradient.

cartridge and type of sorbent). Increasing the sample volume when using  $\text{C}_{18}$  cartridges led to band broadening, while PRP-1 polymeric sorbent provided satisfactory peak shape making feasible the determination of analytes below  $0.1 \mu\text{g l}^{-1}$ .

In comparison with offline methods there are two main limitations when developing online SPE–LC. First, the small columns used obviously contain small amount of sorbent (typically between 20 and 100 mg). Under these conditions, when analytes are poorly retained in the precolumn, the amount of sorbent cannot be sufficiently increased, as in offline SPE procedures, as it would lead to an increase in the precolumn size and unacceptable band broadening. Normally, the best solution is to select a more retentive sorbent. Second, the mobile phase selected should allow the elution of analytes from the precolumn being compatible with the analytical column, and adequate to obtain the chromatographic separation required in each particular case. In practice, the selection of sorbents in the analytical columns has more restrictions than in precolumns. As an example, if many compounds have to be separated over a wide range of polarity in a SPE–LC multiresidue method, highly efficient analytical columns with both water-rich and organic-rich mobile phases are required when conventional detection techniques (fluorescence, ultraviolet–visible) are employed. At present, only  $\text{C}_{18}$  silica columns meet this requirement. In fact, this packing material is the

most widely used as stationary phase in the analytical columns employed in SPE–LC methods.

One advantage of automated online SPE–LC methods is the good reproducibility in comparison with offline methodologies, even when breakthrough volumes are exceeded. Quantification in online SPE–LC should be performed using standards (in solvent or, preferably, in matrix) after application of the whole procedure, under the same experimental conditions than in samples. Therefore, it is not necessary to calculate the recovery of the extraction process for every analyte, as quantitative analysis is not carried out by comparison with direct injections. Of course, it is more convenient to handle a sample volume lower than the breakthrough volume for more reproducible results, but this is not always feasible. For example, in a multiresidue analysis where analytes have to be determined at very low concentration levels, relatively high sample volumes have to be extracted to get satisfactory limits of quantification. Under this situation, polar analytes might not be completely recovered after extraction in the precolumn, but they could be satisfactorily determined, with acceptable reproducible results, in automated SPE–LC procedures.

### Applications and Trends

Nowadays online SPE–LC is a powerful approach for sample preparation, as it satisfies most of analytical demands usually required in modern

laboratories: selectivity, sensitivity, reliability, and rapidity. Simplification of sample preparation is one of the trends in analytical chemistry that is clearly fulfilled by automated SPE-LC. Miniaturization of the overall SPE-LC system reduces analysis time and decreases solvent consumption, two important requirements in the biological field. The development of more selective sorbents is also one of the main research areas, and clear examples are the MIPs or immunoextraction sorbents.

Apart from interesting applications to the biological field (biomedical and pharmaceutical applications), SPE-LC is a very attractive approach in the environmental field, where it has been widely applied mainly because of the improvement in sensitivity. Additionally, it is suited to multiresidue analysis, one of the main trends in the environmental field, as there is an increasing interest in monitoring the environment and preserving the water quality, and increasing the number of analytes to be controlled. At present, the sensitive and accurate determination of a wide range of neutral, acidic, and basic pollutants, and even ionic substances, is a demand in environmental field. The extraction of polar analytes in water is a research area that is being investigated by introduction of new polymers and carbons with high specific surface areas. The identification of transformation products and metabolites of different pollutants in the environment will be a key issue in the next years, and SPE sorbents able to extract these polar analytes will be required. Obviously, all analytical demands in biological, environmental, and any other application field will be better satisfied by using hyphenated techniques, i.e., by coupling MDLC with MS (single or tandem). In fact, SPE-LC (and LC-LC) in combination with MS/MS is one of the most powerful tools for the majority of problems encountered in real-world samples.

## LC-LC Coupling

LC-LC refers to the conventional two-dimensional mode of chromatography using two full-size separation columns where the fractions from one column are selectively and precisely transferred (online or offline) to one secondary column for a further separation. An LC-LC separation system may be used in either the profiling or targeted mode. The purpose of the profiling mode, also known as comprehensive LC-LC, is to fractionate all components of the analyzed mixture, while the purpose of the targeted LC-LC mode is to isolate either a single or a few specific components (that present similar retention on the first dimension) from a complex mixture. Thus, the transferred volume of the first

mobile phase can contain all the components of the sample, a group of peaks, a single peak, or even a fraction of a peak.

### Comprehensive LC-LC

In this approach, the first column is generally operated at either a low-mobile-phase velocity or the flow is interrupted intermittently, while the second column is operated at high velocity to analyze column fractions as they elute from the first column. The rate-limiting step in profiling is analysis time in the second dimension, as it should be able to generate at least one chromatogram during the time required for a peak to elute from the primary column. Thus, apart from other obvious advantages, the use of MS as a detection system is very appropriate in this technique.

Nowadays, the main application area of profiling LC-LC is the proteomic field, where the intention is to characterize the entire range of proteins expressed in a cell or tissue under defined metabolic state, ~10 000–20 000 proteins. Additionally, the proteins are enzymatically cleaved yielding ~20 peptides per protein; so a high-peak-capacity system is required to cope with these extremely complex samples. Various configurations have been proposed for the comprehensive multidimensional chromatography separation of proteins and peptides, mainly size-exclusion chromatography (SEC)/reversed-phase liquid chromatography (RPLC), affinity chromatography (AC)/RPLC, and ion-exchange chromatography (IEC)/RPLC. Other configurations include capillary electrophoresis, used as the second dimension, in combination with SEC or RPLC as first dimension, or isoelectric focusing and chromatofocusing, used as first dimension, coupled with RPLC as second dimension. Coupling IEC to RPLC as first and second dimensions, respectively, is possibly the most frequent approach as it shows several advantages as complementary selectivities, solvent compatibility, and easy coupling of the second column to electrospray tandem mass spectrometry systems, which relaxes the constraints on LC resolution because additional separation also occurs in the mass domain. The majority of chromatographic systems developed in this field employ capillary LC because of the improvement in sensitivity and the easy hyphenation with MS detection systems.

Several strategies have been employed in MDLC separations for proteomic studies. These strategies include discontinuous offline or online MDLC using fraction collection, direct online coupling of two dimensions, and MDLC using column switching. A major advantage of MDLC for proteomic studies

is its ability to fully automate multidimensional LC-MS<sup>n</sup> systems. However, the complete resolution of all components still remains a challenge.

### Targeted LC-LC

In contrast to comprehensive MDLC, the goal of the targeted LC-LC mode is to isolate a single, or a few specific components, from a complex mixture. Target analysis is normally performed in the 'heart-cutting' mode, where an eluting zone from the first column (C-1) is switched online to a second column (C-2) for a subsequent separation of the transferred compounds (Figure 2). This combination leads to an enhanced selectivity and sensitivity, although the use of compatible mobile phases restricts LC-LC to certain chromatographic combinations.

In comparison to automated online trace enrichment on precolumns (SPE-LC), one of the most favorable aspects of automated sample processing using LC-LC is the utilization of the separation power of the first column (C-1). In fact, the application range of the LC-LC technique will be determined by the separation power of the first column: low resolution favors multiresidue methods, while high resolution leads to methods for single analytes or a group of compounds with fairly similar properties.

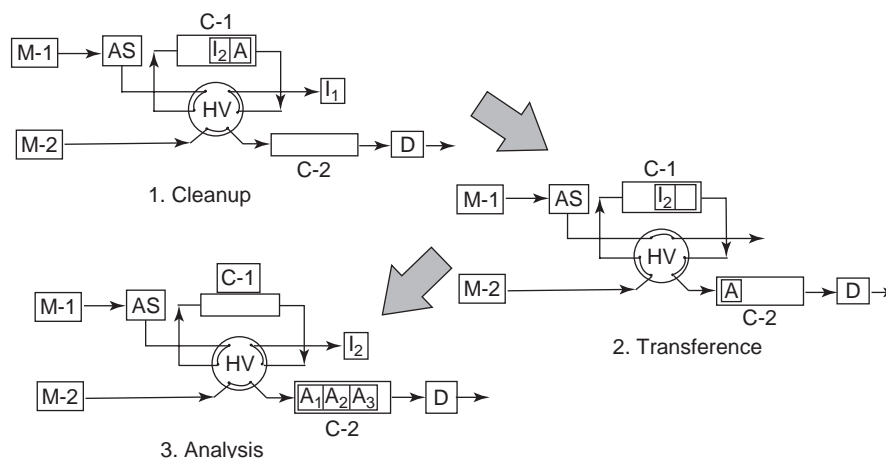

LC-LC offers the opportunity to enlarge the sample injection volume up to several milliliters for improved sensitivity. Additionally, it gives the possibility to remove a large excess of interferences by appropriate selection of the LC-LC conditions (for example, early-eluting polar interferences encountered in environmental samples). This pre-separation on C-1 contributes largely to the enhancement of the selectivity.

**Method development** A critical operation in target component analysis by LC-LC is the selection and transfer of the eluent fraction from C-1 to C-2. Connecting the first column directly to the detector, after injecting a standard solution, the volume of the first mobile phase (M-1) required for the elution of the first analyte gives the cleanup volume/time. On the other hand, the volume of M-2 required to complete the elution of the last eluting analyte is used to estimate the transfer volume.

Usually, the forward-flush mode is preferred for the transfer from C-1 to C-2, although the backflush mode has also been used. The latter has two main drawbacks: (1) it will lead to an additional band broadening when analyzing polar to moderately polar compounds, and (2) for more retained analytes reversing the flow will diminish the separation obtained earlier in the process.

Assuming that analytes retention times and peak widths are constant, the selection of coupling conditions is usually achieved by time-based valve switching. Dirty samples (or extracts) may affect the retention times of analytes on C-1 during the processing of large series of samples. In these cases, due to C-1 column aging and possible increasing peak width, it is recommended to periodically check the heart-cut timing parameters (cleanup and transfer times).

The attainable selectivity will be determined by the effectiveness of cleanup on C-1 for the removal of early-eluting interferences (cleanup time) and by the volume of the analytes fraction (transfer time), which limits the transfer of late-eluting interferences. In other words, optimal selectivity will be obtained at a minimal transfer volume, and part of the required separation should have been taken place in C-1

**Figure 2** Different stages of the LC-LC coupling in the targeted mode using the 'heart-cutting' approach. M-1 and M-2: mobile phases of the first and the second columns; AS: autosampler; C-1 and C-2: first and second columns; HV: six-port high-pressure valve; D: detector; I<sub>1</sub>: early-eluting interferences; A: analytes; I<sub>2</sub>: late-eluting interferences.

before transferring the analyte(s) fraction to C-2. However, in complex samples it is unavoidable that part of the interferences is transferred together with the analytes. Thus, it is important to combine complementary separation mechanisms in the first and second columns to achieve satisfactory separation between analytes and cotransferred interferences.

**Applications** Major applications of targeted LC–LC deal with the biomedical, pharmaceutical, and environmental fields. In biomedical analysis, LC–LC has been used extensively and successfully in the heart-cut mode for the determination of drugs and related compounds in matrices as plasma, serum, or urine. LC–LC of endogenous compounds in biological fluids has also been reported. Chromatographic combinations applied include RPLC, ion exchange, polar bonded-phase, chiral, or affinity columns.

Although the term ‘multidimensional’ refers to LC systems with different retention mechanisms in the columns used, column switching without change in retention mode can be a useful approach, easy to implement, for separating complex mixtures. For example, coupling two RPLC columns is a practical substitute for linear gradient elution and is particularly useful for analyte enrichment and sample cleanup, as has been demonstrated for environmental analysis or bioanalysis.

Most of applications of targeted LC–LC in the environmental field deal with analysis of a single analyte. Thus, various polar ‘difficult’ analytes, as the herbicides bentazone, glyphosate and glufosinate, and pesticides degradation products, as ethylenetiourea, have been successfully determined in water. The effectiveness of this approach is illustrated in **Figure 3**, relative to the determination of MCPA residues using diode array detection (DAD). Using standards, the cleanup time was established to be 3.6 min in the C<sub>18</sub> column used as C-1, and the transfer time 1.3 min for the multiresidue determination of the herbicide MCPA and two of its main metabolites (**Figure 3A**). However, the single analysis of parent MCPA allowed increasing the cleanup up to 4 min, decreasing the transference time to 0.5 min. **Figure 3B** shows the presence of matrix interferences in olive leaves extracts when connecting directly the C<sub>18</sub> column to the detector. The small transfer window used for the single determination of the MCPA still contained a considerable amount of coextracted interferent compounds. However, coupling of this C<sub>18</sub> column (C-1) to a RAM column (C-2) provided satisfactory results allowing the trace-level determination of this herbicide in complex matrices (**Figure 3C**).

In multiresidue analysis, dealing with several analytes with a wide polarity range, larger transfer

volumes are required, and consequently the selectivity is lower. However, the major source of interferences in environmental samples are usually the more polar compounds, as humic and fulvic acids (at least using conventional ultraviolet detection). In these cases, the use of coupled-column RPLC allows the effective removal of these early-eluting interferences. Therefore, multiresidue methods involving large transfer volumes, which, in principle, would lead to less selectivity, can still be quite attractive. Thus, several triazines and their transformation products, or a group of chlorofenoxiacids, have been determined at the sub-ppb levels in environmental samples with minimum sample treatment by using this approach.

## MDLC in Combination with MS

Multidimensional chromatography is one of the best options to prevent unwanted coelutions of analytes with other matrix components present in a variety of complex samples, and also to incorporate automated online sample preparation in the analytical process. Nowadays, well-developed methodologies already exist using multidimensional modes as LC–LC or SPE–LC in combination with spectroscopic or electrochemical detection for the selective and sensitive determination of many analytes, mainly in the biomedical, pharmaceutical, environmental, and food fields.

At present, the selectivity improvement is easily achieved by coupling simple mono-dimensional chromatographic systems to MS. Today, easy-to-operate benchtop MS (/MS) systems (single/triple quadrupole or ion-trap) with robust interfaces are commercially available, and LC–MS(/MS) has become the method of choice in many quantitative bioanalytical and food applications, its use also being increased in the environmental field. In spite of the high selectivity (and sensitivity) of tandem MS techniques, some kind of sample preparation and preseparation still remains necessary in order to avoid the analyte response decrease by matrix effects (ion suppression) observed in the majority of analyte/sample combinations as well as to avoid source contamination by matrix loading.

The use of LC–MS(/MS) could certainly decrease the interest of multidimensionality in many applications, as no highly efficient separations will be normally required. However, extremely complex samples still need the improved peak capacity offered by MDLC. Thus, comprehensive LC–LC in combination with MS(/MS) is one of the most powerful approaches for the entire profiling of proteins and

**Figure 3** (A) LC chromatogram ( $\lambda = 228$  nm) for a mixture of MCPA (1) and its metabolites 4-chloro-2-methylphenol (2) and 4-chlorophenol (3) obtained by injection of a  $400 \text{ ng ml}^{-1}$  standard solution, connecting C-1 ( $30 \times 4.6 \text{ mm ID C}_{18} 5 \mu\text{m}$ ) directly to a DAD detector. Optimization of the LC-LC coupling conditions. (B) LC chromatogram ( $\lambda = 228$  nm) of an olive leaves extract spiked with MCPA at  $4 \text{ mg kg}^{-1}$ , obtained connecting C-1 ( $30 \times 4.6 \text{ mm C}_{18} 5 \mu\text{m}$ ) directly to the detector. (C) LC-LC chromatogram ( $\lambda = 228$  nm) of an olive leaves extract containing  $0.4 \text{ mg kg}^{-1}$  MCPA. A  $30 \times 4.6 \text{ mm}, 5 \mu\text{m}, \text{C}_{18}$  column used as C-1, and a  $50 \times 4.6 \text{ mm}, 5 \mu\text{m}$  ( $100 \text{ \AA}$  pore size) Hisep column used as C-2. Coupling conditions shown in (B).

peptide mixtures of unknown composition. Moreover, the automated and efficient cleanup offered by targeted LC–LC justifies its use in combination with MS/MS systems in the development of advanced and accurate methods with very little sample treatment. As an example, the use of LC–LC–MS/MS has been recently proposed for the rapid determination of low concentration levels of xenobiotics and metabolites in biological human fluids. Additionally, highly diluted samples take advantage of the high sensitivity obtainable by online trace enrichment (SPE–LC). The combination of SPE–LC with MS/MS leads to sensitive and selective analytical methods, which are suitable for the monitoring of a variety of organic micropollutants in environmental waters, as a typical application.

## Introduction

The modern liquid chromatograph appears as an impressive, very elaborate, and technically advanced combination of electronic, mechanical, and hydraulic devices. This impression, however, is a little misleading as, although the overall instrument can be made very complex by the addition of a large number of ancillary devices, the ‘basic’ liquid chromatograph

is relatively simple incorporating well-established standard components. Even in its simplest form, the basic liquid chromatograph can probably still deal with over 80% of all liquid chromatography (LC) applications. In the discussion of LC instrumentation, therefore, the complex versatile instrument will be considered as an embellished form of the basic liquid chromatograph. A diagram of a modern versatile

peptide mixtures of unknown composition. Moreover, the automated and efficient cleanup offered by targeted LC–LC justifies its use in combination with MS/MS systems in the development of advanced and accurate methods with very little sample treatment. As an example, the use of LC–LC–MS/MS has been recently proposed for the rapid determination of low concentration levels of xenobiotics and metabolites in biological human fluids. Additionally, highly diluted samples take advantage of the high sensitivity obtainable by online trace enrichment (SPE–LC). The combination of SPE–LC with MS/MS leads to sensitive and selective analytical methods, which are suitable for the monitoring of a variety of organic micropollutants in environmental waters, as a typical application.

## Introduction

The modern liquid chromatograph appears as an impressive, very elaborate, and technically advanced combination of electronic, mechanical, and hydraulic devices. This impression, however, is a little misleading as, although the overall instrument can be made very complex by the addition of a large number of ancillary devices, the ‘basic’ liquid chromatograph

is relatively simple incorporating well-established standard components. Even in its simplest form, the basic liquid chromatograph can probably still deal with over 80% of all liquid chromatography (LC) applications. In the discussion of LC instrumentation, therefore, the complex versatile instrument will be considered as an embellished form of the basic liquid chromatograph. In this way, as the sample becomes more challenging, it will be clear which specific ancillary equipment will be necessary to achieve the required separation and it will be possible to choose an optimum system based on rational discrimination. A diagram of a modern versatile

**Figure 1** A modern liquid chromatograph.

liquid chromatograph is shown, in block form, in **Figure 1**.

It is seen that the basic liquid chromatograph consists of a solvent reservoir, a pump, a sample valve, column, detector, and a potentiometric recorder. The main differences between the simple device and the versatile instrument is, first, the chromatographer who designs the separation methodology must have a good understanding of molecular interactive

processes between the sample components and the two phases so that the separation can be achieved using a single solvent (i.e., isocratically). Second, the components of the mixture of interest must contain an ultraviolet (UV) chromophore so that it can be detected by a UV detector (or a property appropriate for any other type of detector that might be chosen). Third, the results must be calculated from direct measurements on the recorder chart as opposed to a

computer data acquisition and processing system. The relative advantages of these latter two procedures will be discussed later.

## The Solvent Reservoir(s)

The solvent reservoirs are normally made of glass or stainless steel. Glass reservoirs are usually necessary for ionic mobile phases (such as those used in ion chromatography and 'paired ion' chromatography) to avoid corrosion. If only nonionic solvents are to be used, then stainless steel is quite satisfactory. The reservoir volume can vary from 250 to 1000 ml and each reservoir should be fitted with an appropriate 'sparging' apparatus. Most solvents contain a significant amount of dissolved air (oxygen and nitrogen) and on leaving the column, bubbles are often formed in the mobile phase that, when passing through the detector, can seriously impair its performance. The sparging procedure consists of bubbling a continuous stream of an 'insoluble' gas (e.g., helium) through the solvent that elutes the dissolved gases before entering the column.

Some samples contain solutes that have a wide range of interactivity with the stationary phase. Under such conditions solvent programming may be necessary to elute the more strongly held solutes in reasonable time. Thus, a number of solvent reservoirs may be necessary. Generally, by careful choice of stationary phase and solvents, even challenging separations can often be achieved with only two solvents but, sometimes, for certain difficult mixtures (e.g., chiral separations) very subtle interactions between solutes and solvents may be necessary and three different solvents may be required. It follows that three or more solvent reservoirs will be included in the more versatile chromatograph.

## Solvent Programmers

In the basic chromatograph the solvent flows directly from the reservoir to the pump, in the more versatile solvent systems different solvents are passed to a solvent programmer. The solvent programmer adjusts the flow of each solvent so that, at any given time, the resulting mixture has a known and predefined composition. The program is usually controlled either by the main chromatograph computer or a microprocessor associated with the programmer itself. There are two basic types of programmer, arbitrarily referred to as the 'high-pressure programmer' and the 'low-pressure programmer'. The high-pressure programmer is not commonly used as it requires a pump for each solvent and is, thus, rather expensive. The pumps are actuated by stepping

motors that are supplied with square wave pulses of different frequency that provide different flow rates. The different solvent flows are then passed through a mixer or mixing chamber to the sample valve. The frequency of the square wave pulses is computer or microprocessor controlled. The low-pressure programmer involves the use of a single pump that draws solvent from a series of valves (one valve for each solvent) that are also actuated by square wave pulses. The relative amount of solvent drawn through a valve depends on the period it is open (active) and the period it is closed (inactive) (i.e., the 'mark-to-space' ratio of the square wave). The mark-to-space ratio of the square wave is also computer or microprocessor controlled. The solvent from each valve passes to a mixing chamber and then to the pump. The gradient, gradient form, initial flow rate, and final flow rate are all user defined by the gradient program. Linear, concave, and convex gradient profiles are usually available and reverse gradients facilities are also possible.

## Pumps

Pump deliveries vary with the application for which they are to be used. For general use, flow rates of  $0.1\text{--}10\text{ ml min}^{-1}$  are common but if microbore columns are used then flow rates as low as  $5\text{--}500\text{ }\mu\text{l min}^{-1}$  might be more appropriate. Pumps should operate at pressures up to at least 6000 psi or even 10 000 psi but pressures above these are not practical as sample valves cannot operate for very long at pressures in excess of 6000 psi without leaking. In fact, for a reasonably long life, most sample valves should not be operated continuously much above 3000 psi, which also limits the maximum operating pressure of the pump. There are a number of different types of pump that can provide the necessary pressures and flow rates required by the modern liquid chromatograph. Most chromatographs are fitted with reciprocating pumps actuated by either diaphragms or, more commonly, pistons. Examples of three of the more common pumps employed in contemporary liquid chromatographs are shown in Figure 2.

The single piston reciprocating pump was the first of its type to be used in liquid chromatographs, it is the simplest, the least expensive, and is still very popular today. The single piston pump is shown at the top of Figure 2. The piston is made of synthetic sapphire; in fact, most pistons of modern LC pumps are made of sapphire to reduce wear and extend the working life of the pump. The cylinder is usually made of stainless steel, which incorporates two non-return valves in line with the inlet and outlet connections to the pump. The piston is driven by a

Single piston pump

Rapid refill pump

Twin-headed pump

**Figure 2** Different types of LC pumps.

stainless steel cam that forces the piston into the cylinder expressing the solvent through the exit non-return valve. After reaching the maximum movement, the piston follows the cam where it meets a step and, as a result of the pressure exerted by the return spring, rapidly returns the piston and refills the cylinder. The shape of the cam is cut to provide a linear movement of the piston during expression of the solvent, but a sudden return movement on the refill stroke. In this way the pulse effect is reduced. However, although the pulses are not completely eliminated in this manner, the damping effect of the modern high-efficiency LC column, packed with particles a few micrometers in diameter, ensures that any remaining pulses are strongly attenuated before they reach the detector. In addition, most detector sensors are designed to be both flow and pressure insensitive and so single piston pumps can usually be employed with confidence.

The rapid refill pump, shown at the center of **Figure 2**, consists of two cylinders and a single common piston. The expression of the solvent to the column is depicted in the upper part of the figure. As the piston progresses to the right, solvent is pumped to the column system, but at the same time fresh solvent is being drawn into the right-hand chamber from the solvent supply system. At the point where the piston arrives at the extent of its travel, a step in the driving cam is reached and the piston is rapidly reversed. As a result the contents of the chamber on the right-hand side are conveyed to the left-hand chamber. This situation is depicted in the lower part of the central figure. The transfer rate of the solvent to the left-hand chamber is 100 times as fast as the delivery rate to the column and consequently reduces the pulse on refill very significantly. Furthermore, if a solvent gradient is being used while the right-hand chamber is being filled, excellent mixing is achieved. However, the refill cylinder volume will cause a series of stepped changes in solvent composition during gradient elution instead of a smooth continuous change that may or may not be deleterious to the quality of the separation.

An alternative approach to the removal of pump pulses, which is probably the more successful but, as one might expect, the more expensive, is the use of twin pump heads. In a two-headed pump, one cylinder can be filled, while the other is delivering solvent to the column. The cylinders and pistons of a two-headed pump are constructed in a very similar manner to the single-piston pump with a sapphire piston and a stainless steel cylinder. Each cylinder is fitted with nonreturn valves both at the inlet and the outlet. The cams that drive the two pistons are carefully cut to provide an increase in flow from one pump while the

other pump is being filled to compensate for the loss of delivery during the refill process and, thus, a fall in pressure. A diagram of a twin-headed pump is shown at the bottom of **Figure 2**. It is seen that there is a common supply of mobile phase from the solvent reservoir or solvent programmer to both pumps and the output of each pump joins and the solvent then passes to the sample valve and then to the column. In the diagram, a single cam drives both pistons, but in practice, to minimize pressure pulses, each pump usually has its own cam drive from the motor. The displacement volume of each pump can vary from 20 or 30  $\mu\text{l}$  to over 1 ml but the usual displacement volume is  $\sim 250 \mu\text{l}$ . The pump is driven by a stepping motor and, thus, the delivery depends on the frequency of the supply fed to the motor, which is controlled by a microprocessor or the main computer. Some pumps are fitted with pulse suppressers that can take a variety of forms. Pulse suppressers, however, do introduce extra column volumes in the solvent conduit to the column, which can significantly distort the expected concentration profile during gradient elution.

There are other pumps used in LC. The 'diaphragm' pump is similar to a piston pump except that the piston is replaced by a moving diaphragm. This type of pump is often used in preparative and semipreparative chromatography. One of the early pumps to be used was the 'syringe' pump, which was, in effect, a large, mechanically operated hypodermic syringe. The capacity of this type of pump is limited and, thus, frequently requires refilling. It is now largely used for injecting reagents in postcolumn derivatization. Another pump is the 'pneumatic' pump, which can probably provide the highest pressures. This pump is driven by compressed air and, by using widely different piston cross-sections for the air and solvent cylinders, can provide very large pressure amplification and, thus, very high pressures. This type of pump provides very large pulses when refilling and is now mostly used for column packing.

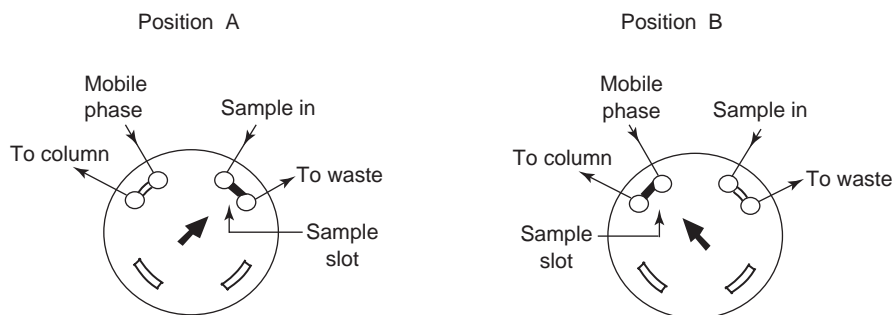

## Sample Valves

There are two types of sample valve in general use in analytical LC: the internal loop valve and the external loop valve. The two types of sample valve are shown diagrammatically in **Figure 3**.

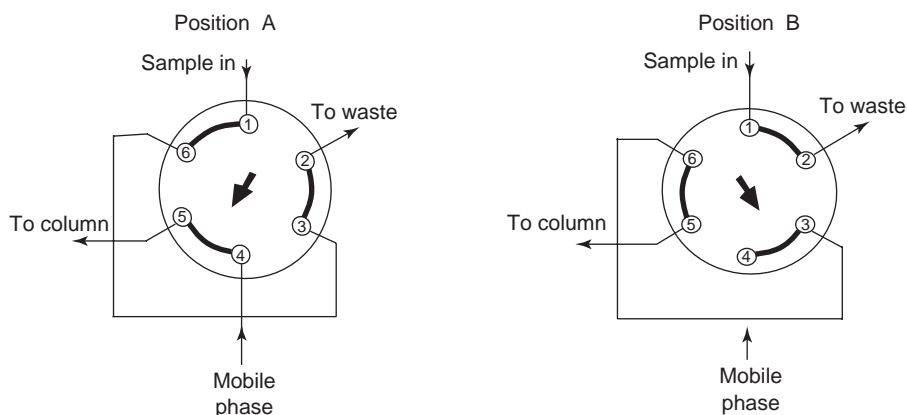

### The Internal Loop Valve

The internal loop valve has only four ports and the sample volume is contained in the connecting slot of the valve rotor. As a consequence, this type of valve is used only for relatively small sample volumes. Internal sample loop valves deliver samples ranging from 0.1 to  $\sim 0.5 \mu\text{l}$  in volume. The operation of the valve

The internal loop valve

The external loop valve

Column-switching valve arrangements

**Figure 3** Different sample valve types.

is depicted in **Figure 3**, the diagram on the left shows the sample being loaded into the valve. The sample occupies the rotor slot on the upper right and has been filled by passing the sample from an appropriate syringe through the rotor slot to waste. While loading the sample, the mobile phase passes through the valve and direct to the column. The valve is then

rotated and the sample position is depicted on the right of **Figure 3**. The valve slot is now imposed between the mobile phase supply and the column and, consequently, the sample is swept onto the column by the solvent. This type of valve is used when the sample volume can have a critical effect on the net peak dispersion. A typical example would be in the

use of short columns, perhaps 4.6 mm in diameter and 2–5 cm long packed with support particles only 3  $\mu$ m in diameter. Alternatively, they would be used with relatively long columns (10–30 cm in length) but only  $\sim$ 1 mm or less in diameter.

It must be emphasized that if the sample contains labile material of biological origin, then all parts of the chromatographic system that can come in contact with the sample must be constructed of a biocompatible material. In practice, this means that every part between the sample valve and the detector should be made from titanium or some other appropriate material such as PEEK, or where there is little or no pressure, Teflon.

### The External Loop Valve

The external sample loop injector is the more popular type of sample valve and has six ports as depicted in **Figure 3**. Three slots are cut in the rotor so that any adjacent pair of ports can be connected. In the loading position shown on the left, the mobile phase supply is connected by a rotor slot to port (4) and the column to port (5), allowing the mobile phase to flow directly through the column. In this position, the sample loop is connected to ports (3) and (6). Sample flows from a syringe into port (1) through the rotor slot to the sample loop at port (6). At the same time the third slot in the rotor connects the exit of the sample loop to waste at port (2).

The sampling position is shown on the right of the diagram. On rotating the valve, the sample loop is interposed between the column and the mobile phase supply by connecting ports (3) and (4) and ports (5) and (6). As a consequence, the sample is swept onto the column by the mobile phase. In the sampling position, the third rotor slot connects the syringe port to the waste port. The sample loop can take a wide range of volumes, those used for analytical purposes usually falling within the range of 1–20  $\mu$ l, but those for preparative separations may be as large as 100 ml or more. Some external loop valves are fitted with a seventh port with a silicone septum on the face of the valve. This allows the sample to be injected directly into the sample loop by a hypodermic syringe.

Samples can be placed on the column in other ways. In preparative chromatography, the sample is often very large and may be pumped directly onto the column from a sample reservoir employing a high-pressure pump similar to that used in the mobile phase supply system. Alternatively, with particularly difficult separations, the sample may be placed on the column from the eluent of a precolumn, using column switching (often described as two-dimensional chromatography). For example, the sample may be first

separated on the basis of molecular size using size exclusion chromatography and, by a suitable valve arrangement, a sample of selected molecular weight may be diverted to a reversed-phase column and the fraction separated on the basis of dispersive interactions. This significantly increases the discriminating capability of the overall chromatography system.

After passing through the sample valve and prior to entering the column, a separate valve can be used to select a particular type of column that can increase the versatility of the liquid chromatograph significantly. An example of a six-port valve arranged for column switching is shown at the base of **Figure 3**. The same valve is used as that for external loop sampling. Column (1) is connected between ports (5) and (6) and column (2) between ports (2) and (3). The mobile phase from a sample valve (or sometimes from another column) enters port (1) and the detector is connected to port (4). In the initial position of the rotor shown in the diagram on the left-hand side, the rotor slots connect ports (1) and (6), (2) and (3), and (4) and (5). This results in the mobile phase passing from port (1) to port (6), through column (1) to port (5), from port (5) to port (4), and out to the detector. Thus, the separation takes place in column (1). The ports connected to column (2) are themselves connected by the third slot and thus isolated. When the valve is rotated, port (1) is connected to port (2), port (3) is connected to port (4), and port (5) is connected to port (6). Thus, the mobile phase from either a sample valve or another column enters port (1) passes to port (2) through column (2) to port (3), then to port (4), and then to the detector. Ports (5) and (6) are connected, this time isolating column (1). This arrangement allows either one of two columns to be selected for an analysis or part of the eluent from another column pass to column (1) for separation and the rest passed to column (2).

For multiple analyses of a routine nature, automatic samplers are often employed. One type consists of a carousel of septum-capped vials containing different samples interspersed by vials containing pure solvent for washing purposes. The septum is automatically pierced by two needles one dipping into the liquid and one dipping only into the air space above the liquid. A small pressure of gas is applied to the air space which forces some liquid through the sampling tube that is connected to a normal external loop sample valve and then passes through the sample loop. After an appropriate time the pressure is removed and the next vial is placed in the sampling position. The valve loop is first washed with solvent then filled with sample that is then injected onto the column by a pneumatic actuator. This procedure is repeated for each subsequent sample.

## Columns

Columns vary widely in size depending on the nature of the sample and the scale of the separation. The radius can range from a fraction of a millimeter to several centimeters and in large-scale separations column diameters may be 10 cm or more. Columns can also vary in length from 2 or 3 cm to a meter. For most analytical separations columns of 2–4 mm ID and 3–25 cm length are used, packed with particles 3–10  $\mu\text{m}$  in diameter. Small diameter columns (1 mm or less) provide the highest mass sensitivity and are used when there is limited sample. Wide columns are used for preparative and semipreparative work. Most stationary phases are bonded to silica although polymeric materials are also very popular. The bonded phase can range in character from strongly dispersive to strongly polar and include anion and cation exchangers. However, the most popular ion-exchange media are based on cross-linked polystyrene beads.

In the early days of LC, the effect of temperature on separations was not considered to be very profound and columns were rarely thermostatted, but operated at room temperature. Over the last decade, however, with the advent of fast, high-efficiency columns and the challenges of very difficult separations (such as those met in chiral chromatography) it was found that temperature can have a very strong effect on retention; particularly 'relative' retention. In fact, although it could be theoretically predicted that in many separations there will be a temperature of co-elution for a given pair of solutes at a particular solvent composition, this was not experimentally verified until the 1980s. It follows that a column oven became an important feature of all liquid chromatographs and that it was advisable to thermostat an LC column to  $\pm 0.5^\circ\text{C}$  for accurate and precise results. All modern chromatographs are fitted with temperature-controlled ovens, many with refrigeration units allowing temperatures ranging from 0 to  $100^\circ\text{C}$  to be employed if so desired.

## Detectors

The detector is a device that senses the presence of a solute in the eluent from a chromatographic column and, thus, the output, suitably presented (for example, on a chart recorder) can display the nature of the separation and permit a quantitative assessment of the sample components. Excluding the column, the detector is the most important component of the liquid chromatograph as its design determines the accuracy and precision of the LC analysis. Many detectors have been developed based on a variety of different sensing principles, but only  $\sim 12$  are

presently used in modern LC and, of those 12, perhaps only four dominate in general use. The more popular four are the 'UV detector' (fixed and variable wavelength), the 'electrical conductivity detector', the 'fluorescence detector', and the 'refractive index detector'. The refractive index, although the least sensitive of the three detectors, is included as it has an almost universal response. It is particularly useful in the detection of polymeric material (particularly biopolymers) as its response is directly proportional to the concentration of the polymer and virtually independent of the molecular weight.

### Detector Specifications

There are seven major detector specifications which are as follows:

- detector linearity,
- linear dynamic range,
- detector noise level,
- detector sensitivity, or minimum detectable concentration,
- pressure sensitivity,
- flow sensitivity, and
- temperature sensitivity.

The two most important specifications are sensitivity (minimum detectable concentration) and linearity.

Detector sensitivity has been defined as the minimum concentration of an eluted solute that can be unambiguously differentiated from the noise. The ratio of the signal to the noise for a peak that is considered decisively identifiable has been arbitrarily chosen to be two (a ratio employed in electronic theory). Thus, the sensitivity or minimum detectable concentration is that concentration that provides a signal equivalent to twice the noise level. Unfortunately, the sensitivity defined in this way will usually depend on the physical properties of the solute used for measurement and, thus, must be defined.

The detector linearity can be defined from the following relationship:

$$v = Rc^\alpha$$

where  $v$  is the output from the detector,  $R$  is a constant, and  $\alpha$  is the 'response index'.

For a truly linear detector the value of  $\alpha$  will be unity, and for accurate quantitative analysis, the value of  $\alpha$  should be between 0.97 and 1.03. The general specifications for the four, more common detectors are given in Table 1.

The detector may be incorporated in the total chromatograph or connected to the column as a separate component. The latter is quite popular as it allows the detector to be changed, if so required, and permits greater flexibility. For preparative work the

**Table 1** Typical specifications for the four commonly used LC detectors

<i>The UV detectors</i>	
Fixed wavelength UV detector	
Sensitivity (toluene)	$5 \times 10^{-8} \text{ g ml}^{-1}$
Linear dynamic range	$5 \times 10^{-8}$ to $5 \times 10^{-4} \text{ g ml}^{-1}$
Response index	0.98–1.02
The multi-wavelength UV detector	
Sensitivity	$1 \times 10^{-7} \text{ g ml}^{-1}$
Linear dynamic range	$5 \times 10^{-7}$ to $5 \times 10^{-4} \text{ g ml}^{-1}$
Response index	0.98–1.02
Typical specifications for a refractive index detector	
Sensitivity (benzene)	$1 \times 10^{-6} \text{ g ml}^{-1}$
Linear dynamic range	$1 \times 10^{-6}$ to $1 \times 10^{-4} \text{ g ml}^{-1}$
Response index	0.97–1.03
Typical specifications for a fluorescence detector	
Sensitivity (anthracene)	$1 \times 10^{-9} \text{ g ml}^{-1}$
Linear dynamic range	$1 \times 10^{-9}$ to $5 \times 10^{-6} \text{ g ml}^{-1}$
Response index	0.96–1.04
Typical specifications for an electrical conductivity detector	
Sensitivity	$5 \times 10^{-9} \text{ g ml}^{-1}$
Linear dynamic range	$5 \times 10^{-9}$ to $1 \times 10^{-6} \text{ g ml}^{-1}$
Response index	0.97–1.03

detector outlet is often connected to a fraction collector. For semipreparative work, this usually consists of a carousel of collecting tubes that can be alternately and automatically filled by the eluent from the detector outlet. The carousel rotation can either be actuated on a time basis or by the detector signal. For large-scale separations, usually only one or two products are of interest, in which case a three-way valve is connected to the detector outlet that can divert the column eluent to waste or to one of two collection vessels. This valve can also be actuated on a time basis or from the detector signal.

## Data Processing and Recording

The best method of recording chromatographic data and its processing depends heavily on the complexity of the sample and the quality of the separation. If the sample is relatively simple, or only a small number of solutes are of interest, and those of interest are well

resolved, then peakheight measurement can be used for quantitative assessment. Under such circumstances, manual measurements (made on the recorder chart) will provide as fast and as accurate an analysis as a complex computer data processing system. In fact, it was shown many years ago that the most accurate results were obtained manually by cutting the peak out of a recorder chart and weighing it. This procedure is, however, very tedious and time consuming and not really practical in modern analytical laboratories. If the sample is complex, however, and the solutes are not completely resolved then, without doubt, computer data acquisition and processing will be, by far, the fastest procedure. The accuracy of the results will, however, depend heavily on the 'quality of the separation' and the 'integrity' of the processing software that may differ significantly from one supplier to another.

It should be emphasized that clever software is no substitute for good chromatography. Good chromatography is attained from a sound, fundamental knowledge of the technique coupled with experience and experimental skill. It is not achieved solely by the astute choice of complex and expensive apparatus.

In fact, it was shown many years ago that the most accurate results were obtained manually by cutting the peak out of a recorder chart and weighing it. This procedure is, however, very tedious and time consuming and not really practical in modern analytical laboratories. If the sample is complex, however, and the solutes are not completely resolved then, without doubt, computer data acquisition and processing will be, by far, the fastest procedure. The accuracy of the results will, however, depend heavily on the 'quality of the separation' and the 'integrity' of the processing software that may differ significantly from one supplier to another.

It should be emphasized that clever software is no substitute for good chromatography. Good chromatography is attained from a sound, fundamental knowledge of the technique coupled with experience and experimental skill. It is not achieved solely by the astute choice of complex and expensive apparatus.

## Introduction

Combined high-performance liquid chromatography–mass spectrometry (LC–MS) was originally

**Table 1** Milestones in the development of combined liquid chromatography–mass spectrometry

1972	First paper on LC–MS by the group of Tal'roze
1974	A variety of LC–MS interfaces presented at the <i>9th International Symposium on Advances in Chromatography</i> , Houston, Texas

1984	Commercial introduction of the thermospray interface
1987	Commercial introduction of continuous-flow fast-atom bombardment
1988	Commercial introduction of ionspray, the heated nebulizer, and the particle-beam interfaces
1990	Commercial introduction of the electrospray interface

developed as an alternative to gas chromatography–mass spectrometry (GC–MS) for those compounds that are not amenable to GC–MS. As such, the field of applications of LC–MS concerns the analysis of highly polar, thermolabile, and/or ionic compounds. The development of technologies to couple LC and MS started in the early 1970s along various lines simultaneously. The coupling of LC and MS takes place by means of a so-called interface, which is a dedicated piece of instrumentation installed onto the mass spectrometer to which the LC system is connected. A variety of LC–MS interfaces have been developed. Important milestones in the development of the LC–MS interface are summarized in **Table 1**.

## Principles

In developing online LC–MS, three major problems require attention: the amount of mobile phase that has to be introduced into the high vacuum of the MS, the composition of the mobile phase, and the nature of the components to be analyzed.

In order to avoid the loss of analyte, either as much of the LC effluent as possible has to be introduced into the mass spectrometer, or efficient analyte enrichment must be achieved in the LC–MS interface. Without modification, only  $\sim 50 \text{ nL s}^{-1}$  of liquid can be introduced into a differentially pumped MS vacuum system. Possible solutions to this flow-rate incompatibility problem are: enlargement of the pumping capacity of the MS vacuum system, removal of solvent prior to the introduction of the analytes into the high-vacuum region, splitting away part of the effluent at the cost of analyte loss, and miniaturization of the internal diameter of the LC column. The currently applied interface, based on atmospheric-pressure ionization (API), is discussed in more detail below.

There are rather severe restrictions with respect to the composition of the mobile phase. Although most

current API interfaces can deal with phosphate buffers in the mobile phase without significant instrumental problems, the use of nonvolatile buffers can lead to problems related to severe adduct formation and signal suppression. For routine operation in LC–MS, mobile phases containing nonvolatile mobile-phase additives, e.g., phosphate buffers, ethylenediaminetetraacetic acid, and ion-pairing agents like tetraalkylammonium ions or alkylsulfonates, are not recommended.

The problems related to the nature of the analytes appeared most difficult in the early years of LC–MS, but meanwhile a variety of so-called soft-ionization techniques have been developed, sometimes as a spin-off or in conjunction with LC–MS developments. Electrospray ionization (ESI) is by far the most successful of these techniques. They allow the mass spectrometric analysis of highly polar, ionic, and (thermo)labile compounds. As a result, the problem can be considered to be solved. In the majority of the liquid-based soft-ionization methods, the analytes, either as neutrals or as preformed ions in solutions, are transferred to the gas phase by nebulization of the liquid and subsequent desolvation of the droplets. In this way, the amount of heat required in the transfer has been minimized, which is favorable for the type of compounds to be analyzed.

LC–MS should be considered as a hybrid technique, in which the features of both LC and MS are optimally used to get the best possible result. Optimum separation conditions in terms of mobile-phase composition and stationary phase for a ultraviolet (UV) detector may widely differ from the separation conditions ideally suiting the mass spectrometer. Unlike in the early days of LC–MS, performing LC–MS in most laboratories is no longer the task of specialized mass spectrometrists. The technique is entering the chromatography laboratory as well. And in many instances separate LC–MS laboratories are set up, where specialists from the two disciplines work together to get the best results.

## LC–MS Interfaces

In the past 10 years, the manner in which LC–MS analysis is performed has significantly changed. While in the past it was necessary to choose the most appropriate LC–MS interface for a particular application from a list of five possibilities, e.g., the moving-belt interface, the direct-liquid introduction interface, the thermospray interface, the particle-beam interface, and the continuous-flow fast-atom bombardment interface, today all LC–MS technologies are based on API. The two most important

techniques are ESI and atmospheric-pressure chemical ionization (APCI); in addition, atmospheric-pressure photoionization is also used.

An API interface consists of five parts (Figure 1):

- the liquid introduction device, where nebulization of the LC column effluent is performed;
- the actual ion source region, where the ions are generated at atmospheric pressure;
- the ion-sampling aperture;
- the atmospheric-pressure to high-vacuum interface: the transition region; and
- the ion-optical system, where the ions generated in the source are analyte-enriched and transported toward the high-vacuum mass analyzer.

The operational principle of an electrospray API interface is as follows.

The column effluent from the LC is nebulized into the atmospheric-pressure ion source region. Typical solvents used are mixtures of water and methanol or acetonitrile, containing up to  $10 \text{ mmol l}^{-1}$  electrolyte, such as formic acid or ammonium acetate. Nebulization can be performed either by means of a strong electrical field, or by a combination of the strong electric field and pneumatic nebulization. The latter is sometimes named pneumatically assisted electrospray or ionspray<sup>®</sup>. The pure electrospray process is limited to flow rates up to  $10 \mu\text{l min}^{-1}$ . Pneumatically assisted electrospray enables the introduction of higher flow rates, up to  $1 \text{ ml min}^{-1}$ . Since ion production mechanisms between the two modes are identical, the term electrospray is used here throughout.

The electrospray nebulization is the result of a 2–5 kV electrical potential applied to the solvent emerging from a capillary. The field pulls out the liquid from the inlet capillary into a conical tip,

frequently called the Taylor cone. At the tip of the cone, one or more fine liquid threads appear, which subsequently disintegrate into small droplets. Uniform droplets in the  $1 \mu\text{m}$  diameter range are produced in a breakup process that results from autorepulsion of the electrostatically charged surface, which overcomes the cohesive forces of surface tension.

In the next step, ions are produced from the evaporating droplets. The processes involved are not completely understood. The general picture is as follows. As a result of the electrospray nebulization process, small charged droplets are generated, positively charged droplets when the source is operated in positive-ion mode and negatively charged droplets in the negative-ion mode. These droplets travel toward the counter-electrode. In the positive-ion mode, this results in transport of positive charges from the inlet capillary, also called electrospray needle, to the counter-electrode, which is the source block in most cases. At the same time, the negative ions are attracted toward the needle. At the needle, oxidation of these negative ions takes place, while reduction of the positive charges takes place at the counter-electrode. In negative-ion mode, this picture is reversed. The counter-electrode contains an  $\sim 200 \mu\text{m}$  ID hole, the so-called ion-sampling orifice, which samples part of the ions generated into the vacuum interface toward the mass analyzer.

In their flight between needle and counter-electrode, the droplets will start to evaporate, which means that neutral solvent molecules are evaporated from the surface of the charged droplets. The charge in the droplets will preferentially sit at the surface of the droplet, in order to achieve minimum interaction between the charges, in accordance with the laws of Coulomb. As a result of the solvent evaporation, the droplet size will decrease, which in turn leads to

**Figure 1** Schematic diagram of an atmospheric-pressure ionization interface.

shorter distances between the charges at the surface of the droplets. This process of solvent evaporation will continue as long as the surface tension of the liquid can accommodate the Coulomb repulsion between the charges. When this is no longer possible, a so-called Coulomb explosion will take place. The process, also called field-induced electrohydrodynamic droplet disintegration, results in the emission of a number of microdroplets with a radius of less than 10% of that of the initial droplets.

With these microdroplets, the solvent evaporation process will continue. Another Coulomb explosion may follow, leading to further reduction of the droplet size. The microdroplets play an important role in the analyte ionization. However, there are two theoretical models describing the actual ionization event, leading to gas-phase ions amenable to MS. In both models, the concept of preformed ions in solution plays an important role.

In the mid-1960s, Dole and co-workers were the first to combine electrospray nebulization with MS. Their hypothesis was that the nebulization of a dilute protein solution would lead to gas-phase protein ions as a result of continued solvent evaporation and Coulomb explosion. This would in the end lead to a very small droplet containing only one charged protein molecule. This small droplet can be considered as a solvated protein ion. Desolvation of this ion by solvent evaporation results in a gas-phase protein ion. This model is nowadays called the charge-residue model.

When, 15 years later, the Nobel-prize laureate Fenn and his co-workers continued the work of Dole with other analytes than proteins, they found results not in agreement with the charge-residue model. Therefore, they adopted another model, described in the mid-1970s by two Canadian scientists Iribarne and Thomson. In this so-called ion-evaporation model, it has been thermodynamically demonstrated that ions may escape from a sufficiently small droplet with a sufficient number of charges. This model also requires the analyte to be present as a preformed ion in solution.

Significant research has been done to prove the correctness of either of these models and/or to falsify one of them. From these studies, it appears that both models contribute to ion formation in ESI. The importance of either effect depends on the analyte. Therefore, ESI is best considered as a mixed-mode ionization. Some effects are more readily explained from the charge-residue model, some other from the ion-evaporation model. An important prerequisite for both models is that analytes should be present as preformed ions in solution. This indicates an analytical strategy to enhance the analyte ionization

in electrospray – adjust the solvent pH to stimulate the formation of either protonated or deprotonated molecules for organic bases and acids, respectively.

Unfortunately, this picture got corrupted when data were shown of good ESI performance for organic bases in positive-ion mode from basic solutions. This so-called wrong-way-around electrospray indicates that yet another mechanism will be operative. Nebulization of analyte solutions was initially adopted in LC–MS to achieve a gentle transfer of neutral molecules from the liquid phase to the gas phase by soft desolvation, which is a process similar to the processes described by the charge-residue model, but now for neutral species. Gas-phase ion–molecule reactions between these neutral analyte molecules and ion-evaporated buffer ions, for instance,  $\text{NH}_4^+$ , will also lead to protonated molecules. It appears that this gas-phase chemical ionization rather than the liquid-phase process is just another process involved in ESI. A summary of the ionization processes is given in **Figure 2**.

Whatever the exact mechanism is, the ionization leads to the formation of either positive or negative gas-phase ions, which move toward the ion-sampling orifice. In practice, we can only sample a very small portion of the ions produced. However, the ions are not expected to reach the ion-sampling orifice as a free gas-phase ion. In the humid ion source, the gas-phase ion is expected to be solvated. This solvated ion, which can be considered as a very tiny droplet, will pass through the ion-sampling orifice toward the skimmer and through the radio frequency (RF)-only multipole element. In this vacuum transition region, the solvated ion must be desolvated again, which is due to many ion–molecule collisions, with solvent and nitrogen molecules in the transition region. Ionic

**Figure 2** Summary of the electrospray ionization process.

species like  $[M + \text{MeCN} + \text{H}]^+$  at  $m/z$   $M + 42$ , which are sometimes observed, can be considered to be due to insufficient desolvation of the analyte ion.

Different instrument manufacturers have developed a variety of source designs. Important design characteristics in this respect are:

- the position of the spray probe relative to the ion sampling orifice, which is nowadays orthogonal in most cases;
- the manner in which heat is applied to assist in the evaporation of the solvent, e.g., by concurrent, orthogonal, or countercurrent-heated nitrogen gas;
- the type of ion-sampling orifice, e.g., an orifice in a flat plate, a cone, or a capillary, and the means to protect the orifice against clogging;
- the presence of ion-optical devices between ion-sampling orifice and skimmer;
- the position of the skimmer relative to the ion-sampling orifice; and
- the type of RF-only multipole device present in the second (and eventually third) vacuum chamber, e.g., quadrupole, hexapole, octapole, or ion tunnel.

Although such design characteristics can lead to significant different performance for a particular analyte, which in solving particular analytical problems may direct the selection of the instrument of that particular manufacturer, in general all systems currently commercially available show adequate performance in LC–MS. Discussing these differences in detail is beyond the scope of this article.

Next to ESI, APCI is an alternative, especially for less polar compounds. The APCI interface consists of a different solvent inlet probe, the so-called heated nebulizer, and a discharge electrode, but uses exactly the same atmospheric-pressure ion source and vacuum transition region as in ESI (see **Figure 1**). In a heated nebulizer, the LC column effluent is first pneumatically nebulized into an aerosol, which subsequently is evaporated in a heated vaporizer zone. Solvent and analyte vapor meet the discharge needle, where a potential of a few kilovolts initiates a continuous discharge that results in the ionization of solvent molecules, which in turn ionize the analyte molecules by gas-phase ion–molecule reactions (common chemical ionization processes).

## Qualitative and Quantitative Analysis

LC–MS can be used for both qualitative and quantitative analysis. A large number of examples

have been described in the literature. In this respect, it must be emphasized that the availability of LC–MS interfaces also enables the rapid introduction of samples into the mass spectrometer, e.g., by means of an autosampler, without online chromatographic separation. This approach has, for instance, been applied for the rapid screening of combinatorial libraries and rapid molecular-weight determination of synthetic products during multistep organic synthesis.

LC–MS has been used in qualitative analysis in a wide variety of fields. The most important application areas comprise:

- pesticides, herbicides, and insecticides;
- environmental contaminants such as sulfonated azo dyes, surfactants, antifouling agents, and drugs;
- support of drug development within pharmaceutical industry, i.e., in drug discovery, identification of metabolites, reaction by-products, and degradation products;
- steroids and steroid conjugates;
- natural products such as alkaloids, flavonoids, mycotoxins, and neurotoxins; and
- biochemically important compounds such as prostaglandins, peptides, proteins, (phospho)lipids, (oligo)saccharides, and (oligo)nucleotides.

Furthermore, LC–MS is used in a wide variety of other identification studies, e.g., in the identification of impurities and by-products in bulk chemicals used in industry, in the characterization of frequently applied fluorescent derivatives for LC in combination with fluorescence detection, for studying simulated biochemical processes via online electrochemical conversion units, and mass spectrometry via an LC–MS interface.

Identification is primarily based on molecular-mass determination, while for an actual structure elucidation LC–MS must be used in combination with tandem mass spectrometry (MS–MS). ESI and APCI are soft-ionization techniques, generating only intact molecule-derived ions, but no fragment ions for most molecules. Therefore, it is frequently applied in combination with MS–MS to achieve more structural information. With respect to qualitative analysis, the use of electrospray LC–MS–MS for peptide sequencing as part of proteomics research is currently an important area.

Although quantitative analysis can be based on the response for an intact molecule-derived ion, e.g., the protonated molecule, in most cases MS–MS is applied as well. In that case, the MS–MS is operated in the so-called selected-reaction monitoring mode

(SRM). In this mode, the first MS stage is used to select the ion of the intact molecule of interest from all other ions generated in the source, e.g., ions due to coeluting interferences from a complex matrix. The selected  $m/z$  is collided with neutral gas to induce fragmentation in a process called collision-induced dissociation (CID). While in product-ion scan mode the second MS stage is scanned to obtain the product-ion mass spectrum, in the SRM mode only one structure-specific  $m/z$  is transmitted to the detector. The SRM mode is the most selective generally applicable detection mode available – one will only get a signal when after sample pretreatment and LC within a particular retention time window, a molecule is present which is ionized to the  $m/z$  selected in the first MS stage, subsequently fragmented by CID to the  $m/z$  selected in the second MS stage. SRM is routinely applied in many studies for quantitative analysis. It is, for instance, the method of choice in analytical support of preclinical and clinical studies during drug development by pharmaceutical industries.

Similar to GC–MS, isotopically labeled internal standards can be used in quantitative analysis by LC–MS. Examples are given in the section below.

## Selected Applications

Environmental analysis is another important application area of LC–MS. The analysis is often a multiresidue strategy directed at many different compounds from various compound classes. A good example is the screening of surface and ground waters for environmental contamination prior to their use in the production of drinking water. According to European regulations, the determination of any individual pesticide at the level of  $0.1 \mu\text{g l}^{-1}$  is required. Both quantitation and identification is required at this level. Detection of pesticides at these levels can only be achieved by the use of preconcentrating sample pretreatment, e.g., offline or online liquid–liquid extraction or solid-phase extraction (SPE), in combination with selected-ion monitoring or SRM. Such a procedure is obviously not a general screening procedure. In addition, the various compound classes show quite different responses in ESI or APCI, e.g., some compounds should be analyzed in positive-ion mode, while others only provide sufficient response in negative-ion mode.

A typical approach in environmental analysis is an integrated system called SAMOS, which enables the automated, unattended analysis of filtered 100 ml surface water samples by means of online SPE and subsequent gradient-LC–UV detection. Any

compound-detected by a SAMOS system must be confirmed and/or identified by LC–MS. In this step, a more target-compound oriented approach can be applied. SAMOS-like systems can be coupled online to an LC–MS interface, as, for instance, demonstrated for a priority group of pesticides by the group of Barceló. An example of a chromatogram obtained with the application of this method to 200 ml of tap water spiked with 15 pesticides from various compound classes at  $0.04 \text{ ng ml}^{-1}$  level each is shown in Figure 3.

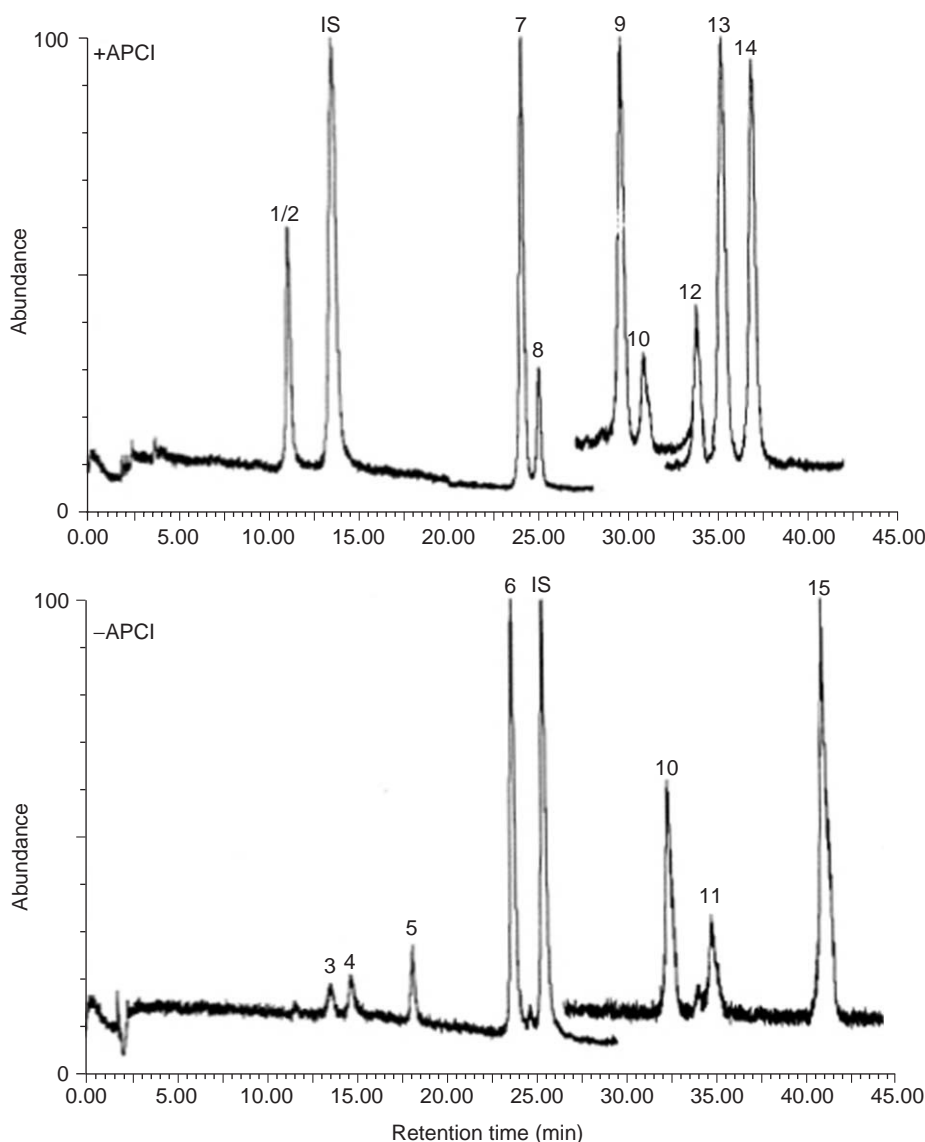

Due to its sensitivity, selectivity, and potential analysis speed, LC–MS is a tool of utmost importance in virtually every stage of drug development. The role of LC–MS already starts in the drug discovery stage. Three powerful tools have been developed for LC–MS to support in drug discovery.

The first and most generally applicable tool is Open Access, which transforms an LC–MS system into a walk-up ‘black-box’ for synthetic chemist in need of a rapid confirmation of the good progress of their synthesis by molecular-mass determination of their product.

To a growing extent, drug discovery is based on synthesis by combinatorial chemistry procedures. The combinatorial libraries need to be screened for biological activity, while a rapid characterization of identity is also required. LC–MS technology is frequently applied for the latter step. The analytical system consists of an  $x$ – $y$  autosampler, enabling sample introduction from a 96-well plate, connected to a fast LC–MS system. The software allows the rapid analysis of large series of samples at a high sample throughput, i.e., up to 60 samples per hour. The data-processing software provides a data browser, which allows rapid answers on whether or not the expected products are present. In some applications, the screening for biological activity and the mass spectral characterization is combined into one system by the application of integrated biodetection systems based on antigen–antibody or ligand–receptor interaction.

The third tool combines the rapid screening of combinatorial libraries or of a series of extracts from natural products to preparative-scale purification of biologically active compounds. The fractionation is controlled by the response of the compound of interest in the LC–MS.

While the structure confirmation in these approaches is primarily based on the molecular mass of the intact compound, more elaborate structure elucidation is required in subsequent stages of drug development, i.e., the stages related to impurity screening, identification of drug metabolites, and the search for degradation products in drug substances

**Figure 3** SPE–LC–APCI–MS chromatogram of 200 ml tap water spiked with  $0.04 \text{ ng ml}^{-1}$  of pesticides and  $0.05 \text{ ng ml}^{-1}$  IS (*tert*-butylazine in positive-ion mode and dinoterb in negative-ion mode). Peak identification: 1, bentazone; 2, Vamidothion; 3, 4-nitrophenol; 4, MCPA; 5, mecoprop; 6, dinoseb; 7, atrazine; 8, isoproturon; 9, ametryn; 10, malathion; 11, fenotrothion; 12, molinate; 13, prometryn; 14, terbutryn; and 15, parathion-ethyl. (Reprinted with permission from Aguilar C, Ferrer I, Borrull F, Marcé RM, and Barceló D (1998) Comparison of automated on-line solid-phase extraction followed by liquid chromatography–mass spectrometry with atmospheric-pressure chemical ionization and particle-beam mass spectrometry for the determination of a priority group of pesticides in environmental waters. *Journal of Chromatography A* 794: 147–163; © Elsevier.)

and drug formulations. A comprehensive and multi-instrument strategy for the screening and identification of drug metabolites has been outlined by Clark and co-workers. This approach is readily applicable to impurities and degradation products as well. In the first step, the MS and product-ion MS–MS spectrum of the parent drug is acquired and interpreted using a triple-quadrupole instrument. Discussion with toxicologists and molecular modeling results in a list of expected metabolites. This list

and the interpretation of the MS–MS spectrum enables the design of a number of precursor-ion scan and neutral-loss scan experiments to screen biological samples for metabolites using the triple-quadrupole instrument. In the third step, product-ion MS–MS spectra are acquired for the metabolites in the previous step. At this stage, interpretation of these data starts. Most likely, the interpretation will not lead to unambiguous identification of all metabolites found. Further studies can be performed

in the steps four and five – structure elucidation by multiple stages of MS–MS on an ion-trap instrument, and accurate mass determination of metabolites and product ions in the MS–MS spectra using a hybrid quadrupole–time-of-flight instrument. The final step involves a complete interpretation of the data, synthesis of the metabolites identified, checking of these by further MS–MS and NMR studies.

In addition to these qualitative studies, quantitative bioanalysis, e.g., in preclinical and clinical studies to provide pharmacokinetic and pharmacodynamic data, is an essential part of drug development. Quantitative bioanalysis is the most important application area of LC–MS, in terms of number of instruments applied and the number of analyses performed. Fast, high-throughput, and routine quantitative analysis by LC–MS also demands fast and automated sample pretreatment strategies and advanced data-processing software.

The keys to the success of LC–MS in quantitative bioanalysis are: (1) typical detection limits in the picogram and in favorable cases even subpicogram range, (2) excellent selectivity against possibly interfering compounds in the biological matrix by the use of the SRM mode, (3) enhanced confidence of identity of the compound(s) analyzed, and (4) the ability to use the ideal internal standards: isotopically labeled compounds. LC–MS–MS is often as easy to operate as LC–UV–PDA, but provides better selectivity. As a result, LC–MS–MS has become the method of choice in quantitative bioanalysis within pharmaceutical industries.

The higher selectivity achievable due to the use of SRM procedures is often immediately given away by decreasing the quality of the sample pretreatment and/or the chromatography. The rationale of this is an increase in the sample throughput. Advanced and selective sample pretreatment methods are often time consuming and thereby limit the sample throughput.

Serious matrix problems may be experienced in quantitative bioanalysis, especially in ESI. Signal suppression due to unknown matrix interferences is often observed. Changes in the sample pretreatment procedures may be successful in solving the problem, but in some cases changing over to APCI, when applicable, appears to be the only feasible solution.

ESI is frequently applied in the various stages of the characterization of peptides and proteins: molecular mass determination, amino acid sequencing, determination of nature and position of chemical and posttranslational modifications of proteins, investigation in protein tertiary and quaternary conformations, and the study of noncovalent associates. In most cases, no online separation is applied, but the sample solution is introduced directly via the ESI or

nano-ESI interface. Impressive results have been achieved in this area. Multidimensional LC in combination with MS–MS is rapidly becoming an important alternative to two-dimensional gel electrophoresis in proteomics research.

LC–MS is applied in many other fields as well, e.g., in the study of natural products, such as in the dereplication of flavonoids and several other compound classes in plant material and the identification and quantification of natural toxins, of endogenous compounds like acylcarnitines and arachidonic acid metabolites, and DNA adducts. LC–MS has become a routinely applicable technique. It is rapidly entering the chromatography laboratories to act as an LC detector in a variety of analyses. As such, LC–MS is appreciated for its sensitivity and selectivity, its specificity, and the information obtained, e.g., on the molecular mass of the analyte. The operation of an LC–MS system is no longer reserved to the MS specialist.

### Introduction

Fourier-transform infrared (FTIR) spectroscopy deals with the quantitative measurement of the absorption of IR radiation by a compound. FTIR exhibits molecular–vibrational transitions and provides characteristic information on molecular structure. Therefore, the combination of liquid chromatography (LC) and FTIR, in principle, can be highly useful when specific detection or identification of separated compounds is required. The high speed and multiplex nature of FTIR allows spectra to be recorded at any point in the chromatogram, and during or after the LC separation software can be used to calculate a total IR-absorbance based chromatogram (via Gram–Schmidt vector orthogonalization) or to reconstruct functional-group chromatograms at one or more specific wavelengths.

The combination of LC and FTIR has been a subject of research for more than 25 years now. In the development of LC–FTIR techniques, two basically different coupling methodologies can be discerned, namely one that involves flow cells and one that involves solvent-elimination. In the flow-cell approach, the eluent is led directly through a flow cell where IR spectra are recorded continuously offering fast and relatively easy detection of eluting analytes. The significant IR absorption of the eluent, however, may obscure large parts of the IR spectrum and dictates the use of small optical pathlengths. The solvent-elimination approach involves an evaporation interface for the removal of the interfering eluent and subsequent analyte deposition onto a suitable substrate, prior to FTIR detection of the analyte. In this case, detection is no longer affected by the IR characteristics of the mobile phase and

full spectra of relatively low amounts of compound can be obtained. The challenge of an effective solvent-elimination technique lies in the simultaneous eluent evaporation and analyte deposition, while maintaining the integrity of the obtained LC separation. This article provides an overview of the principles, practical aspects, and current status of LC–FTIR covering both flow-cell and solvent-elimination interfaces.

### Flow-Cell Interfaces

Flow cells offer a simple and straightforward means for the online coupling of LC and FTIR. The effluent of the LC is passed directly through a flow cell and IR spectra are acquired on-the-fly. The merits of the approach include low cost, instrumental simplicity, ease of operation, low maintenance, and the possible use of nonvolatile buffers. The analyte can be studied without any orientation or crystallization effects, oxidative degradation, or evaporation, which might occur upon collection and storage after solvent elimination. Furthermore, flow-cell detection takes place in real time making it potentially useful for online reaction monitoring and fast IR detection. On the other hand, the dynamic nature of on-the-run IR measurements leaves less time to collect spectra, limiting the signal-to-noise ratio (SNR) and sensitivity.

Despite simplicity of flow-cell LC–FTIR, its major drawback is the rather limited choice of eluents. For example, water strongly obscures most of the mid-IR region, prohibiting a practical combination of reversed-phase (RP)-LC and FTIR via a flow cell. Only some organic solvents (e.g., chloroform), which show sufficient transparency in (parts of) the IR spectrum, can actually be used. This essentially limits the application area of flow-cell LC–FTIR to normal phase (NP)-LC, size-exclusion chromatography (SEC), and critical chromatography (CC). Gradient elution cannot be applied, as accurate background subtraction with changing eluent composition is virtually impossible.

### Introduction

Fourier-transform infrared (FTIR) spectroscopy deals with the quantitative measurement of the absorption of IR radiation by a compound. FTIR exhibits molecular–vibrational transitions and provides characteristic information on molecular structure. Therefore, the combination of liquid chromatography (LC) and FTIR, in principle, can be highly useful when specific detection or identification of separated compounds is required. The high speed and multiplex nature of FTIR allows spectra to be recorded at any point in the chromatogram, and during or after the LC separation software can be used to calculate a total IR-absorbance based chromatogram (via Gram–Schmidt vector orthogonalization) or to reconstruct functional-group chromatograms at one or more specific wavelengths.

The combination of LC and FTIR has been a subject of research for more than 25 years now. In the development of LC–FTIR techniques, two basically different coupling methodologies can be discerned, namely one that involves flow cells and one that involves solvent-elimination. In the flow-cell approach, the eluent is led directly through a flow cell where IR spectra are recorded continuously offering fast and relatively easy detection of eluting analytes. The significant IR absorption of the eluent, however, may obscure large parts of the IR spectrum and dictates the use of small optical pathlengths. The solvent-elimination approach involves an evaporation interface for the removal of the interfering eluent and subsequent analyte deposition onto a suitable substrate, prior to FTIR detection of the analyte. In this case, detection is no longer affected by the IR characteristics of the mobile phase and

full spectra of relatively low amounts of compound can be obtained. The challenge of an effective solvent-elimination technique lies in the simultaneous eluent evaporation and analyte deposition, while maintaining the integrity of the obtained LC separation. This article provides an overview of the principles, practical aspects, and current status of LC–FTIR covering both flow-cell and solvent-elimination interfaces.

### Flow-Cell Interfaces

Flow cells offer a simple and straightforward means for the online coupling of LC and FTIR. The effluent of the LC is passed directly through a flow cell and IR spectra are acquired on-the-fly. The merits of the approach include low cost, instrumental simplicity, ease of operation, low maintenance, and the possible use of nonvolatile buffers. The analyte can be studied without any orientation or crystallization effects, oxidative degradation, or evaporation, which might occur upon collection and storage after solvent elimination. Furthermore, flow-cell detection takes place in real time making it potentially useful for online reaction monitoring and fast IR detection. On the other hand, the dynamic nature of on-the-run IR measurements leaves less time to collect spectra, limiting the signal-to-noise ratio (SNR) and sensitivity.

Despite simplicity of flow-cell LC–FTIR, its major drawback is the rather limited choice of eluents. For example, water strongly obscures most of the mid-IR region, prohibiting a practical combination of reversed-phase (RP)-LC and FTIR via a flow cell. Only some organic solvents (e.g., chloroform), which show sufficient transparency in (parts of) the IR spectrum, can actually be used. This essentially limits the application area of flow-cell LC–FTIR to normal phase (NP)-LC, size-exclusion chromatography (SEC), and critical chromatography (CC). Gradient elution cannot be applied, as accurate background subtraction with changing eluent composition is virtually impossible.

**Figure 1** Principle of a transmission zero-dead volume microbore LC-FTIR flow cell (cross-sectional view). (Reprinted with permission from Johnson CC and Taylor LT (1984), *Analytical Chemistry* 56(14): 2642–2647; © American Chemical Society.)

### Flow-Cell Types

Three types of flow cells can be discerned for online LC-FTIR coupling, and these are respectively based on transmission, attenuated-total-reflection (ATR), or specular reflection measurements. The spectral range (i.e., detection wave number range) of these interfaces is determined by the IR characteristics of the applied cell-window material and by the mobile phase used for the chromatographic separation.

The most frequently used type of flow cell is the transmission cell, which can either consist of an IR-transparent cavity or two IR-transparent windows separated by a metal or Teflon spacer. The LC eluent enters and exits the cell via capillary tubing and is sampled by the IR beam passing perpendicularly. Depending on the application, the optical pathlength can be adjusted, ranging from 0.001 to 2 mm. Transmission flow cells are available from several manufacturers and can include high-temperature options. For use in microbore LC, specially designed zero-dead volume flow-cells with an internal volume of 0.33  $\mu\text{L}$  have been developed (Figure 1). The eluent is led through a sample cavity consisting of a 0.75 mm hole drilled in a block of potassium bromide or calcium fluoride. The IR beam interrogates the eluent stream under  $90^\circ$  yielding detection limits in the range of 40–50  $\mu\text{g}$  when chloroform is used as mobile phase.

The second category of flow cells is based on the ATR principle. The cell consists of a cylindrically shaped ATR crystal with cone-shaped ends (Figure 2). The crystal is incorporated in a flow cell with the cone ends outside the cell body and the eluent can enter the flow-cell cavity surrounding the crystal. Cassegrain optics are used to focus the IR beam on

**Figure 2** Principle of an ATR flow cell.

the crystal at one end, and to collect the IR radiance emerging from the other end and direct it toward the detector. To maintain an effective optical pathlength, the number of reflections in the optical element is typically 10 or 11 and the internal volume of the flow cell is 1–25  $\mu\text{L}$ . Spectra collected from ATR flow cells may exhibit typical bandshape distortion due to the refractive-index changes around absorption bands, complicating spectral interpretation. In addition, the wavelength-dependent penetration depth of IR radiation complicates quantitation. However, ATR techniques can be very useful when spectral information from aqueous eluents has to be obtained, as the optical pathlength (i.e., penetration depth) is in the low micrometer range, thereby limiting the absorption by the eluent.

The third type of flow cell is based on specular reflection measurements and consists of a trough-shaped stainless-steel cell body, covered with an IR-transparent window (Figure 3). An external mirror is used to direct the IR beam toward the flow cell under near-normal incidence angles, reducing the reflection losses at the air-window interface. The IR beam is

reflected via a mirror surface inside the cell cavity and directed toward the detector via a second external mirror. The actual optical pathlength actually is twice the thickness of the sample cavity and can be adjusted from 50  $\mu\text{m}$  to 2 mm (cell volumes, 1–40  $\mu\text{l}$ ). AABSpec (Waterford, Ireland) supplies this type of cells.

The commonly used detector-cell volumes, though much smaller than required to minimize band broadening in conventional LC, render flow-cell FTIR detection compatible with miniaturized LC systems. In microbore-LC chromatographic peak volumes are several orders of magnitude smaller and peak concentrations are higher than in conventional LC. However, the sample capacity (both in mass and volume) of LC columns decreases in proportion to their cross-sectional area and the advantage of microbore-LC therefore is only partly fulfilled.

**Figure 3** Principle of a reflection flow cell. 1, cell body; 2, IR-transparent window; 3, flow-cell cavity; 4, LC-flow path; 5, IR-beam path.

### Cell Window Materials

Cell windows or crystals are available from many materials and the choice depends on the application (Table 1). The materials must be chemically resistant to the eluent used in the chromatographic method, withstand high pressures, and offer sufficient transmittance to maintain a reasonable IR-energy throughput. Calcium fluoride ( $\text{CaF}_2$ ), zinc selenide ( $\text{ZnSe}$ ), and, to a lesser extent, germanium ( $\text{Ge}$ ), are frequently applied, but rather expensive flow-cell materials. Potassium bromide ( $\text{KBr}$ ) and sodium chloride ( $\text{NaCl}$ ) are cheap alternatives and offer complete transparency in the mid-IR range. Besides, their low refractive indices minimize the risk of spectral fringes at certain optical pathlengths. However, these materials cannot resist excessive pressures and their strongly hygroscopic properties limit their use to nonaqueous eluents. High refractive index materials (like  $\text{ZnSe}$ ) are required in ATR flow cells in order to maintain total reflection at the crystal boundaries and allow sufficient reflections.

### Eluent Absorption

Ideally, the mobile phase used in flow-cell LC–FTIR should not exhibit serious background absorption that may obscure analyte absorption bands. Unfortunately, most organic solvents used in LC – highly chlorinated and fluorinated solvents being the exception – show intense IR spectra. Furthermore, in frequent cases the choice of eluent is largely determined by the required chromatographic properties of the involved solvent(s). As a consequence, the obtainable qualitative and molecular information often is limited and determined by the spectral window(s) provided by the eluent. The magnitude of solvent

**Table 1** Optical and physical properties of window materials for use in IR flow cells and as deposition substrate in solvent-elimination interfaces

Material	Transmission range ( $\text{cm}^{-1}$ )	% Transmittance (thickness)	Refractive index (at $1000\text{ cm}^{-1}$ )	Hardness ( $\text{kg mm}^{-2}$ )	Sensitive to	Solubility in water
Calcium fluoride ( $\text{CaF}_2$ )	50 000–1111	90.0 (4 mm)	1.39	158	Ammonium salts, acids	Slightly soluble ( $0.013\text{ g l}^{-1}$ )
Germanium ( $\text{Ge}$ )	5500–475	50 (2 mm)	4.0	550	Sulfuric acid, aqueous reagents	Insoluble
Potassium bromide ( $\text{KBr}$ )	40 000–400	90.5 (4 mm)	1.52	7	Lower alcohols, water	Highly soluble
Sodium chloride ( $\text{NaCl}$ )	40 000–625	91.5 (4 mm)	1.49	15	Lower alcohols, water	Highly soluble
Zinc selenide ( $\text{ZnSe}$ )	20 000–454	65 (1 mm)	2.4	137	Acids, strong alkalis	Insoluble

absorption can be decreased by adjusting the optical pathlength of the cell, although this obviously will affect the analyte absorbance too. The optimum pathlength also depends on the analytical query at hand. For example, when specific, accurate, and sensitive detection of an analyte is required at a particular wave number where the solvent shows absorption, an optical pathlength resulting in an eluent absorption of  $\sim 0.4$  AU (i.e., a transmission of  $e^{-1}$ ) would be selected, because then an optimum SNR is obtained. On the other hand, when the primary goal of the experiment is the characterization or identification of the analyte(s), an optical pathlength is chosen in such a way that the eluent absorptions are minimized throughout the spectrum in order to ensure all characteristic absorption bands can be detected for reliable structure elucidation. Clearly, there is always a trade-off between structural information and high sensitivity, and there is no single pathlength suitable for all eluents used in LC. For organic solvents typical optical pathlengths are 100–2000  $\mu\text{m}$  while much shorter optical pathlengths (10–50  $\mu\text{m}$ ) have to be used for water.

In order to correct for background absorption by the eluent, background subtraction often can be carried out quite reliably. Provided that isocratic LC is used, the analytes are present in a constant matrix (eluent) and IR bandshifts due to changes in environment are absent. In addition, FTIR allows the acquisition of spectral data on a precise wave number scale. However, one must be aware of 'ghost bands' or spikes in the region where the eluent is completely opaque leading to the faulty interpretation that there is analyte absorption.

To circumvent problems associated with excessive eluent absorptions that prohibit FTIR transmission detection, some remedies are possible. ATR flow cells can be used to inherently reduce the optical pathlength. Another option is postcolumn extraction of the LC effluent in order to transfer the analytes to a more IR-transparent solvent. Also, deuterated solvents could be used in which eluent absorption bands are shifted to lower wave numbers and potential analyte absorption bands are revealed.

A more recent option to cope with eluent absorption is the increase of the IR source intensity using quantum cascade lasers operating in the mid-IR region. Though molecular structure information cannot be obtained when using a monochromatic source, quantitative measurements of specific functional groups can be achieved. The powerful emission of the IR laser allows larger optical pathlengths to be used in combination with aqueous eluents and improves the SNR with a factor of 50.

**Applications** Notwithstanding the limitations, there are a limited number of specific applications in which flow-cell LC-FTIR can be quite useful to obtain specific quantitative and structural information in a convenient manner. The application area of flow-cell FTIR is limited to samples with relatively high analyte concentrations, as is the case in, for instance, the analysis of carbohydrates, alcohols, and organic acids in wines and sugars in soft drinks. SEC, as used for the separation of synthetic polymers, is also well suited to be coupled with FTIR by flow cells. Polymer samples are often available in large quantities and low detection limits are usually not required. In addition, the separation process in SEC is essentially independent of the choice of eluent, provided the sample is fully soluble and no analyte-stationary phase interactions take place. Consequently, IR-favorable eluents can be selected. Therefore, SEC-flow-cell-FTIR is a valuable tool for the rapid, selective, and quantitative analysis of the chemical composition of polymers as a function of their hydrodynamic volume.

## Solvent-Elimination Interfaces

The strong IR absorption of most eluents reduces the attainable detection limits in flow-cell FTIR and has directed LC-FTIR research toward a solvent-elimination approach in which the eluent is removed prior to detection. To accomplish this, generally the eluent is directed to a nebulizer, often aided with (heated) nebulizer gas, to achieve solvent evaporation. Almost simultaneously, the separated analytes are deposited (immobilized) on a moving substrate to collect the analytes individually and retain the chromatographic integrity. After deposition, IR spectra from the immobilized chromatogram are acquired. Dependent on the type of substrate used (see below) and/or size of the deposited spots, for detection often special optics, such as a (diffuse) reflection unit, a beam condenser, or an IR microscope, are used.

Solvent-elimination LC-FTIR offers a number of distinct advantages when compared with flow-cell LC-FTIR approaches. First of all, the absence of interfering eluent absorption bands permits spectral interpretation over the full wave number region, thereby fully exploiting the identification possibilities of IR spectroscopy. Secondly, the chromatogram is still available after the chromatographic run has completed, and accordingly, the sensitivity (SNR) and/or spectral resolution can be greatly enhanced by employing increased scanning times. Besides, the sensitivity can be further increased by producing concentrated analyte deposits in combination with appropriate IR optics. These aspects make

solvent-elimination the LC–FTIR methodology of choice when structural information of relatively small amounts of analyte has to be obtained. Finally, solvent-elimination interfaces may offer the possibility of gradient LC by varying the nebulizer temperature during the chromatographic run to obtain a constant deposit quality.

### Deposition Substrates and Spectral Quality

Deposition of analytes in solvent-elimination LC–FTIR is performed on powdered substrates, mirrors, or IR-transparent windows. Correspondingly, diffuse reflection Fourier-transform infrared (DRIFT) detection, reflection–absorption (R–A) spectroscopy, or transmission measurements are applied to investigate the analyte deposits.

In early solvent-elimination interfaces, powdered potassium chloride (KCl) was used as substrate. DRIFT, being one of the most sensitive IR modes, was subsequently used for detection and sub-microgram detection limits could be achieved. However, when the eluent is not completely evaporated during analyte deposition, the remaining eluent can draw analyte into the underlying powder layers, which cannot be penetrated by the interrogating IR beam thereby frustrating the detection. Moreover, the homogeneity of the powder, the nature, and load of sample, and the reorientation of the powder surface during deposition may strongly affect the quality and reproducibility of the IR spectra acquired. Furthermore, KCl cannot be used with aqueous eluents, and thus not with RP-LC. As an alternative diamond powder can be used, but this is very expensive and difficult to recycle.

Water resistant, front-surface aluminum mirrors can be used as deposition substrates, followed by spectral acquisition in the R–A mode. The smooth and hard surface properties of mirrors complicate efficient analyte deposition (spreading of the analytes) when the eluent is not completely evaporated. The spectral data recorded from these substrates should be in close resemblance to the spectra obtained from transmission measurements, because the band intensities are controlled by a double-pass transmittance mechanism. However, still spectral differences between R–A and KBr disk spectra can be observed, including absorption-band shifts and asymmetries. Furthermore, the effect of light scattering (Christiansen effect) may become apparent when the spot thickness exceeds a certain level and anomalous relative band intensities may be observed in R–A spectra of certain analytes deposited on flat substrates when compared to transmission spectra acquired from KBr disks. In order to minimize these

effects, a rear-surface aluminum-coated IR-transparent germanium disc can be used as deposition substrate, although the adverse spectral effects are never completely eliminated. A postdeposition annealing procedure with dichloromethane has been proposed in order to minimize the effect of light scattering and to produce homogeneous deposits (Figure 4).

Most favorable spectral results in solvent-elimination LC–IR are obtained when analytes are deposited on flat IR-transparent substrates (ZnSe,  $\text{CaF}_2$ , KBr) and measured in the transmission mode. Preferably, ZnSe is used as deposition substrate as this material is inert and insoluble in water (favoring application in RP-LC) and offers a wide transmission range (Table 1). The transmission spectra acquired from analytes deposited on ZnSe are of good quality, free from spectral distortions, show a better SNR than R–A spectra of the same amount of material, and closely resemble KBr-disc transmission spectra allowing reliable spectral interpretation and automated library searches.  $\text{CaF}_2$  can be used as a cheap alternative when no spectral information has to be obtained in the low wave number region.

The quality and appearance of spectra are influenced by the morphology and thickness of the deposited analytes. The morphology will depend primarily on parameters such as eluent composition, evaporation rate, temperature, and nature of the substrate and the analytes. During solvent evaporation some compounds will form nice crystals while

**Figure 4** Overlay of IR spectra obtained from polystyrene deposit on Ge–Al substrate before (top) and after (bottom) dichloromethane vapor annealing demonstrating the effect on IR scattering. (Reprinted with permission from Johnson Schunk TC, Balke ST, and Cheung P (1994) *Journal of Chromatography A* 661: 227–238; © Elsevier.)

others will deposit as an amorphous layer. Over time, the morphology can change to its energetically most favorable state. Analyte morphology must be taken into consideration, as library entries may contain analyte spectra only with a particular morphology. Analyte deposits may be well defined to form a smooth film, whereas other analytes may form discontinuous spots showing many small irregular domains. Due to this spatial inhomogeneity, it can be difficult to obtain a continuous chromatogram with an IR microscope, as empty substrate areas may be sampled by the narrow IR beam. Alternatively, scanning over a larger substrate area using less beam-condensing optics can average out the spatial inhomogeneity, although the sensitivity may be compromised. Effective and distinct deposition of low-viscosity and liquid-like compounds may be a problem when hard and smooth substrates are used. Spreading and remixing of these analytes can be accomplished by deposition/trapping in the pores of either low-density polyethylene or polytetrafluoroethylene membranes as supplied by Lab Connections (Northborough, MA, USA).

### Types of Solvent-Elimination Interface

Considering the variety of solvent-elimination interfaces developed over the past decades, substantial efforts have been made to accomplish successful evaporation of the LC eluent and subsequent deposition of analytes. Early interfaces employed KCl powder as substrate for DRIFT detection. The LC eluent was dropped via a heated tube into discrete KCl-filled cups and residual solvent was removed by aspiration before acquisition of spectra. These early LC-DRIFT systems have demonstrated for the first time that solvent-elimination LC-FTIR is more sensitive and produces spectra of better quality than flow-cell-based LC-FTIR. However, the drawbacks of DRIFT discussed previously redirected the focus on the use of flat deposition substrates. In the first designs of this kind, small flows ( $<5 \mu\text{l min}^{-1}$ ) of organic solvents from micro-LC columns were led directly to a moving KBr plate that was placed under a stream of warm nitrogen to enhance solvent evaporation. After deposition, analyte spectra were acquired by IR transmission detection. In this setup, the complete chromatogram was stored as a continuous trace, but the analyte spots obtained on the KBr plate were quite large leading to a rather poor IR sensitivity.

In order to permit higher (aqueous) flow rates ( $>5 \mu\text{l min}^{-1}$ ) in LC-FTIR, use of interfaces with an enhanced evaporation capacity are essential. As effective solvent elimination is an important issue as

well when LC is combined with mass spectrometry (MS), several LC-MS interface types have also been utilized for LC-FTIR. For instance, the thermospray interface has been used to evaporate aqueous eluents at  $0.5 \text{ ml min}^{-1}$  and simultaneously deposit separated analytes on a metal IR-reflective ribbon that is continuously moved through an FTIR spectrometer equipped with a reflection accessory for spectra acquisition. Detection limits were in the low-microgram range. The particle beam interface originally developed for LC-MS was successfully used for the deposition of LC-separated compounds on KBr substrates. Aqueous eluents could be effectively evaporated at flow rates of up to  $0.3 \text{ ml min}^{-1}$ , and microgram-amounts of analytes (including thermolabile compounds) could be analyzed using FTIR transmission detection. Micro-LC-FTIR via an electrospray interface is also possible: flow rates of up to  $20 \mu\text{l min}^{-1}$  can be eliminated while depositing analytes on a ZnSe plate. Although the potential usefulness of LC-MS interfaces for solvent-elimination LC-FTIR has been demonstrated, the developed systems have never really matured and essentially were used by their designers only.

Most successful solvent-elimination LC-FTIR is achieved by employing pneumatic nebulization (Figure 5). These nebulizers use a high-speed gas flow to break up the eluent into small, fast-moving droplets, thereby greatly enhancing the solvent evaporation. In this way, organic eluents can be readily eliminated, while the nebulizer gas is heated when (almost) complete removal of aqueous eluents is required. Following eluent evaporation, the analytes are deposited on a step-wise or continuously moving IR-transparent substrate. Depending on the focusing capacity of the nebulizer, deposition trace widths of 200–500  $\mu\text{m}$  are achieved, resulting in IR detection limits in the sub-microgram range. Several LC-FTIR designs based on pneumatic nebulization are commercially available from Lab Connections. A rotating germanium disc with a rear-surface reflective coating is utilized as deposition substrate in combination with a reflection accessory for IR measurements.

With pneumatic nebulization for LC-FTIR, optimum mass sensitivity is achieved when microbore-LC (typical flow rate,  $20\text{--}50 \mu\text{l min}^{-1}$ ) is used in combination with a ZnSe deposition substrate and IR microscopy for detection. With such systems it is possible to acquire full spectra from 1 to 10 ng of analyte. In order to achieve complete evaporation of 100% aqueous eluents, enhanced solvent elimination power is required. One solution to this problem is the placement of the nebulizer inside a vacuum chamber to facilitate the evaporation of water. Another option is the online liquid-liquid extraction of the LC eluent

(A)

(B)

**Figure 6** Schematic representation of a piezoactuated flow-through microdispenser interface.

with a volatile organic solvent that, after phase separation, is being directed to the pneumatic interface. An additional advantage of this approach is that nonvolatile buffers can be used in the LC eluent since they are not extracted. Further reduction of the LC flow rate to  $1\text{--}2\ \mu\text{L min}^{-1}$  while adding a make up flow of  $20\ \mu\text{L min}^{-1}$  of methanol is also a way to handle highly aqueous eluents. Then, evaporation

**Figure 7** FTIR spectra of isomeric chloropyrenes recorded during solvent-elimination LC–FTIR of a chlorinated pyrene sample. Based on the spectral data (from the top downward) the isomers could be identified as 1,6-dichloropyrene, 1,8-dichloropyrene, and 1,3-dichloropyrene, respectively.

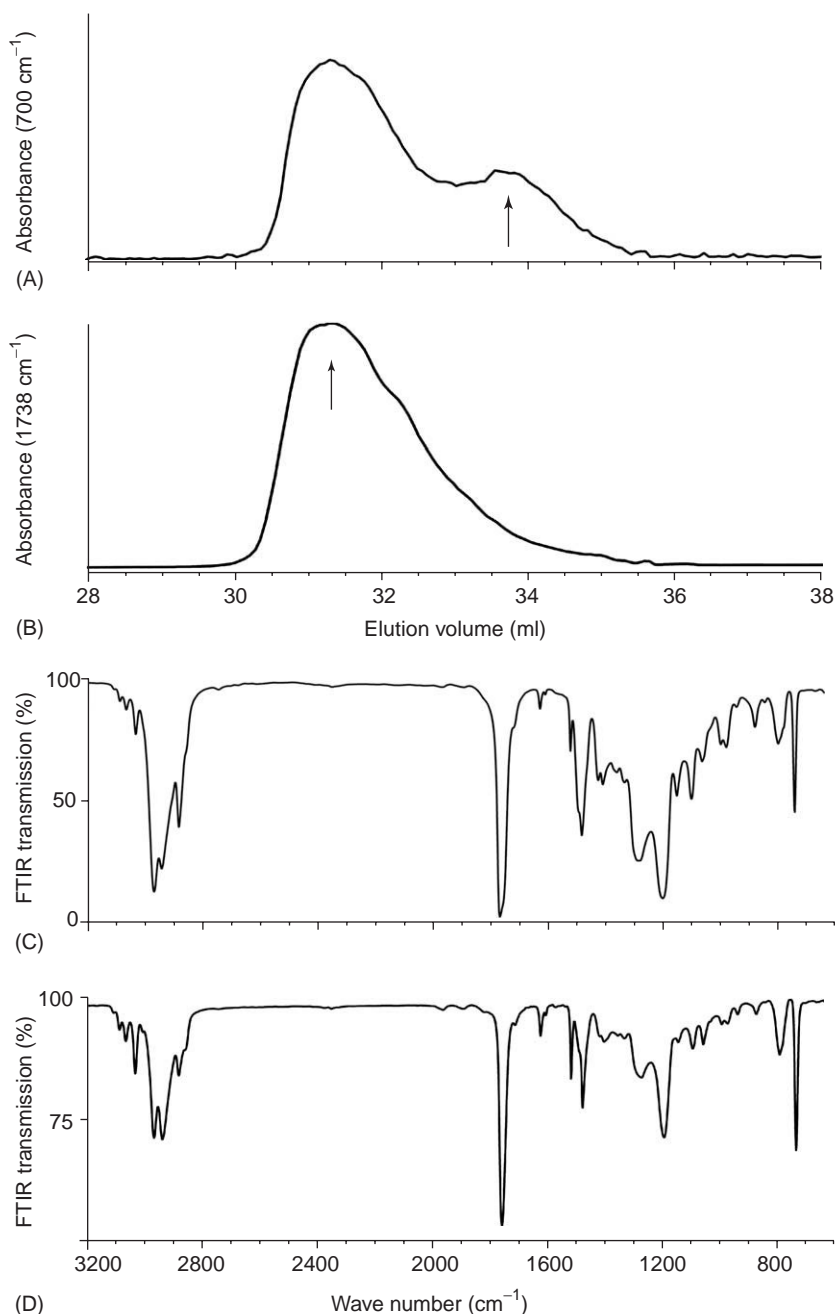

conditions are essentially independent of the water content and even gradient elution can be used.

Next to pneumatic nebulization, ultrasonic nebulization can be applied for solvent-elimination LC–FTIR. The eluent spray is now formed by disrupting the liquid surface at ultrasonic frequencies. Carrier gas can be used to enhance eluent evaporation and to focus the spray toward the deposition substrate. A further increase in the evaporation capacity is accomplished by placing the ultrasonic nebulizer and substrate in a vacuum chamber. Such a system is suitable for the evaporation of high-boiling eluents at relatively high flow rates ( $100\text{--}200\ \mu\text{L min}^{-1}$ ). Various manufacturers have commercialized ultrasonic nebulizers for LC–FTIR: Lab Connections offers the LC Transform 300 Series

and The InfraRed Chromatograph is manufactured by Bourne Scientific (Acton, MA, USA). The latter utilizes an additional desolvation chamber for elimination of the LC eluent.

As mentioned earlier, the most favorable sensitivity in LC-FTIR is achieved when analytes are deposited on the IR substrate in compact spots, because then the advantages of IR microscopy can be fully exploited. Effectively evaporating a stream of eluent

and, at the same time, depositing analytes in a narrow trace is not an easy task, but developments in this direction are ongoing. This is illustrated, for example, by the use of a state-of-the-art piezoactuated flow-through microdispenser in the analysis of glucose and fructose by LC-FTIR. The interface is based on the principle used for inkjet printing and its design has been adapted to operate in the flow-through mode for the use in LC (Figure 6). The

**Figure 8** Solvent-elimination SEC-IR from poly(styrene-butylacrylate) revealing changes in chemical composition as function of hydrodynamic volume. droplets produced by the interface are 53 pl in volume and are readily evaporated at room temperature and atmospheric pressure without additional heating or nebulizer gas, offering mild deposition conditions. As a result the deposits are concentrated in 40–80  $\mu\text{m}$  narrow spots on a deposition substrate of calcium fluoride, which perfectly meets the dimensions for optimum detection by IR microscopy.

### Application

The LC–FTIR detection limits obtained with pneumatic and ultrasonic nebulizers are sufficient for a number of practical applications. For real trace analysis, a sample enrichment procedure such as solid-phase extraction prior to LC–FTIR will be necessary to allow analyte detection. Nevertheless, the usefulness of solvent-elimination LC–FTIR has been successfully demonstrated in a variety of analytical queries where structural information and/or identification of (unknown) compounds are required. The wide range of compounds analyzed by LC–FTIR employing eluent removal comprises environmental pollutants (polycyclic aromatic hydrocarbons, pesticides, and herbicides), pharmaceuticals (e.g., steroids and analgesics) and their impurities, drug metabolites, polymer additives, dyes, and fullerenes. FTIR detection can be especially useful when isomeric compounds have to be distinguished (Figure 7). Even the secondary structure of proteins, such as  $\beta$ -lactoglobulin and lysozyme, has been studied by solvent-elimination LC–FTIR. This technique can be particularly beneficial in synthetic-polymer analysis in order to reveal the chemical composition of (co-)polymers (Figure 8). A special application area is high-temperature SEC–FTIR for the analysis of polyolefins (e.g., composition determination of ethylene–propylene rubbers) with the high-boiling trichlorobenzene as eluent.

The choice for the type of LC–FTIR coupling (flow cell or solvent-elimination) depends on the particular application of the user, where aspects such as type of spectral information needed, required sensitivity, and ease of use are main criteria. Flow-cell LC–FTIR is relatively simple and straightforward, and has developed into a special-purpose technique that can be used in a routine fashion for the monitoring of major mixture constituents with specific functional groups. Solvent-elimination LC–FTIR is somewhat more complicated requiring (sometimes complex) evaporation interfaces, but allows characterization of minor sample components with a high level of confidence. At present, the practical application of FTIR detection in LC is still quite limited.

Nevertheless, developments over the last years have led to the situation that almost every type of LC has been and can be effectively coupled to FTIR. Furthermore, there always will be particular applications (e.g., discrimination of isomers or polymer analysis) where IR data on separated compounds can be highly valuable. Furthermore, for the solution of complex analytical problems, the possible integration of the information on molecular structure provided by FTIR, MS, and/or nuclear magnetic resonance (NMR) would be highly advantageous. Illustrative for this statement is the recent development of hyphenated systems employing multiple interfacing of the same LC system to several spectrometric detectors (UV absorbance, MS, NMR, and FTIR). It is the complementary nature of the data provided by each spectrometric technique that leads to an enormous information content of the total system.

### Introduction

The coupling of high-performance liquid chromatography with nuclear magnetic resonance spectroscopy (LC/NMR) is one of the most powerful methods for the separation and structural elucidation of unknown compounds in mixtures. The recent progress in pulse field gradients and solvent suppression, the improvement in probe technology, and the construction of high-field magnets have given a new impulse to this technique which has emerged since the mid-1990s as a very efficient method for the on-line identification of organic molecules. It took nearly 20 years to establish LC/NMR and this long period can be mainly attributed to the intrinsic low sensitivity of NMR. LC/NMR represents an interesting complementary technique to LC/UV/MS for on-line identification of LC peaks. Recent applications have demonstrated its usefulness in various fields of analytical chemistry.

### NMR Flow Cell Design

The heart of an LC/NMR system includes a dedicated continuous-flow probe. In a classical NMR

experiment, compounds of interest are dissolved in a deuterated solvent and the sample is rotated in a 5 mm i.d. tube to eliminate field inhomogeneities (Figure 1A). With modern NMR instrument the tube is not rotated anymore since for highly sophisticated two-dimensional (2D) experiments rotation causes severe distortions. The design of continuous-flow NMR probes for cryomagnets, introduced in the early 1980s, was in contradiction with this classical conventional tubes setup. In this case, a U-type glass tube was fixed in the dewar of the NMR probe body, breaking the central symmetry of the magnetic field. The first application of this design ('saddle'-shaped geometry) (Figure 1B) showed, however, an excellent resolution approaching those registered with the rotation of the NMR tubes. Saddle-shaped continuous-flow NMR probes for routine applications employs detection volumes between 40 and 120  $\mu\text{L}$ , which are much larger than conventional ultraviolet (UV) detection volumes (8  $\mu\text{L}$ ).

The use of such important detection volumes resides on a compromise that has to be made between the needs for chromatography and those required by NMR. Indeed, while conventional high-performance liquid chromatography (HPLC) can accommodate detection volumes of 5–10  $\mu\text{L}$ , NMR needs extremely large detection volumes for two reasons: (1) line-shape quality and (2) sensitivity.

1. Line-shape quality: When operated in the flowing mode (on-flow), there is a distinct residence time

**Figure 1** Schematic of (A) conventional NMR probes, (B) saddle-type continuous-flow LC/NMR probes, and (C) solenoidal continuous-flow LC/NMR probes. (Reproduced with permission from Albert K (2002) *On-line LC–NMR and Related Techniques*. Chichester: Wiley; © John Wiley & Sons Ltd.)

(dwell time:  $\tau$ ) of the nuclei in the NMR detection cell which has to be considered. This factor was not affecting the standard NMR experiment since nuclei were staying for infinite time period in the tube. In LC/NMR,  $\tau$  is defined by the ratio of the detection volume to the flow rate. If  $\tau$  is below 5 s a line broadening of the NMR signal will be observed which will reduce the NMR spectral resolution. For example, the measured signal half-width of chloroform at 400 MHz will be of 0.55 Hz if the flow is stopped, of 0.75 Hz with a flow of  $0.5 \text{ ml min}^{-1}$  and 1.05 Hz at  $1.0 \text{ ml min}^{-1}$ . In order to maintain a tolerable line broadening the detection volume of the LC/NMR probe was  $44 \text{ }\mu\text{l}$  in this case, which gives a residence time  $\tau$  of 5.28 s at  $0.5 \text{ ml min}^{-1}$ .

2. Sensitivity: The second reason is that LC/NMR is a volume-sensitive detection technique and requires maximization of NMR-active nuclei by extension of the detection volume. The concentration in later LC eluting peaks due to the diffusion of the LC chromatographic process is reduced by a factor of at least 3 and NMR detection of these dilute solutions would require very high detection volumes in the milliliter range.

The design of the actual flow cells thus results in a compromise between needs for resolution and sensitivity on the NMR side (large volume) and reasonable LC peak separation on the chromatographic side (small volume).

### Small-Volume LC/NMR

With the constant need for analysis in the smaller domains, challenges for inherently insensitive methods such as LC/NMR become increasingly severe. Indeed, in the downscaling from  $200 \text{ }\mu\text{l}$  to  $20 \text{ nL}$ ,

10 000-fold fewer spins are present for a given concentration which causes severe sensitivity problems. In this respect, the development of small-volume radiofrequency (RF) probes has experienced a renaissance in the last decade. The design of these microliter-scale probes consists mainly in a microcoil wound directly on to a capillary tube which acts as both a sample container and a coil form (Figure 1C). The fabrication material used has near-zero magnetic susceptibility for decreasing linewidth, improving lineshape and S/N. The LC flow axis of these cells is perpendicular to the magnetic field  $B_0$ , contrary to the conventional LC/NMR probes of larger volume which adopt the saddle-type geometry (Figure 1B). These new microliter-scale probes operating with nanoliter volumes are becoming commercially available and offers interesting possibilities for sample-limited applications.

### Experimental Arrangement

From a practical point of view, a standard LC/NMR experiment can be performed on an NMR system with magnet field strength higher than 9.4 T ( $^1\text{H}$  resonance frequency of 400 MHz) with a dedicated flow-probe and a standard HPLC system. In conventional setups, the HPLC system will be installed at 2–4 m from the magnet; however, with shielded magnets it can be installed directly close to it. The main constraint will be the installation of a valve before the probe for the recording of continuous- or stop-flow spectra (Figure 2). Indeed, while LC/NMR was originally designed for continuous-flow NMR acquisition, the need for full structural assignment of unknown constituents led to major applications in the stop-flow mode, which enable the recording of 2D correlation experiments referred to in this article later.

**Figure 2** Typical setup used for on-flow and direct stop-flow LC/NMR experiments. The control of the stop-flow valve is achieved by the computer of the LC/UV system which triggers both the valve of the HPLC pump and the NMR acquisition computer. A calibrated delay is used for parking the LC-peak of interest with precision at the center of the LC/NMR flow probe.

## Practical Considerations

### Solvent Signal Suppression

The main problem of LC/NMR is the difficulty in observing analyte resonances in the presence of the much larger resonances of the mobile phase. This problem is even worsened in the case of typical LC reversed-phase operating conditions, where more than one protonated solvent is used and where the resonances change frequencies during analysis in the gradient mode. Furthermore, the continuous flow of sample in the detector coil complicated solvent suppression. These problems have now been overcome thanks to the development of fast, reliable, and powerful solvent suppression techniques. These techniques are mainly:

- presaturation (NOESY presaturation);
- soft pulse multiple irradiation; and
- WET (water suppression enhanced through  $T_1$  effects) presaturation.

All these techniques can be used either in the continuous- or the stop-flow mode. WET, in particular,

consists of a combination of pulsed field gradients, shaped RF pulses, and shifted laminar pulses. By varying the tip angle of the selective RF pulses, the WET sequence can be optimized. This sequence provides a fast and efficient saturation of multiple solvent resonances. It can be used in combination with  $^{13}\text{C}$  decoupling for efficient removal of the  $^{13}\text{C}$  satellites of the solvent, which will otherwise strongly affect the spectral quality. An example of the application of the WET sequence for suppression of multiple signals from solvent and ion-pair reagents is shown in Figure 3 for the analysis of GDP-mannose (1).

The main drawback of these solvent suppression procedures is that the analyte signals localized under the solvent resonances will also be suppressed and thus the whole range of  $^1\text{H}$ -NMR signals are not directly observable. This can be a major drawback when dealing with unknown constituents. In order to detect all analyte signals, one alternative is to carry out the solvent suppression in two independent solvent systems such as MeCN– $\text{D}_2\text{O}$  and MeOH– $\text{D}_2\text{O}$ . Such an approach is shown for the analysis of hepatotoxic pyrrolizidine alkaloids in the crude

**Figure 3** Multiple suppression of solvent and ion-pair reagents in the LC/NMR spectrum of GDP-mannose with the WET sequence. (A) Stop-flow spectrum recorded without solvent suppression, solvent signals and ion-pair reagents hinder the detection of the signals of the analyte GDP-mannose. (B) Stop-flow spectrum of GDP-mannose (1) (200  $\mu\text{g}$ , NT = 1024) with suppression of all signals due to the LC eluent. (Reprinted with permission from Ramm M, Wolfender J-L, Queiroz EF, Hostettmann K, and Hamburger M (2004) Rapid analysis of nucleotide activated sugars by high performance liquid chromatography coupled with diode-array detection, electrospray ionization mass spectrometry and nuclear magnetic resonance. *Journal of Chromatographic A* 1034:139–148; © Elsevier.)

**Figure 4** Stop-flow spectra measured for senecionine (**2**) in the lipophilic extract of *Senecio vulgaris* (Asteraceae) in both MeCN–D<sub>2</sub>O and MeOH–D<sub>2</sub>O solvent systems. HPLC conditions: Inj. 3 mg; Col. Symmetry C-18 (150 × 3.9 mm i.d., 5 μm); (A) MeOH–D<sub>2</sub>O gradient (10:90 to 70:30 in 30 min); (B) MeCN–D<sub>2</sub>O gradient (5:95 to 50:50 in 20 min); 0.015 mol l<sup>−1</sup> NH<sub>3</sub>; 0.8 ml min<sup>−1</sup>. LC/NMR conditions: flow cell (60 μl, 3 mm i.d.), 500 MHz. (Reproduced with permission from Wolfender J-L, Ndjoko K, and Hostettmann K (2001) The potential of LC–NMR in phytochemical analysis. *Phytochemical Analysis* 12: 2–22; © John Wiley & Sons Ltd.)

extracts of *Senecio* species (Figure 4). In this case, the LC/<sup>1</sup>H-NMR analyses performed in both solvent systems have enabled the recording of the whole range of <sup>1</sup>H-NMR signals after combination of the information found in both spectra. For senecionine (**2**), the signals in MeCN–D<sub>2</sub>O corresponding to H-14a and H-6b were hidden by the suppression of the acetonitrile signal (Figure 4B) while these resonances were, however, clearly visible when LC/NMR was performed in MeOH–D<sub>2</sub>O.

One way to overcome the problem of solvent suppression is to perform the separation in fully deuterated solvents. This, however, cannot be envisaged routinely on standard HPLC columns, operated at typical flow rates of 1 ml min<sup>−1</sup>, due to the cost of deuterated solvents. Nevertheless, separations may be envisaged on micro or capillary columns, which have a very low solvent consumption. Another alternative consists in column-trapping on solid phase extraction (SPE) and back-flushing into the LC/NMR flow cell using an appropriate deuterated solvent (SPE-NMR), which will yield very 'clean' spectra.

#### HPLC Conditions

In comparison with LC/UV or LC/MS analyses, the on-column loading for LC/NMR is of several orders

of magnitude higher. In order to achieve the best sensitivity, the goal is to bring the highest amount of separated analyte in the lowest elution volume into the LC/NMR cell. Ideally, the chromatographic peak elution volume should be equivalent to the NMR flow cell volume (see above). For crude plant extract analysis, for example, the amount injected on-column can be of several milligrams while only a few micrograms are necessary for LC/UV. In order to cope with these important sample loadings, long HPLC columns (250 mm) or columns with an important diameter (8 mm) are used for standard LC/NMR measurements. In consequence, specific chromatographic conditions have to be developed for LC/NMR in order to separate large amounts of sample with satisfactory LC resolution and maintain flow conditions compatible with the detection cell used.

Most of the applications are performed under typical reversed-phase HPLC conditions. Nondeuterated solvents such as MeOH or MeCN are used. Great care in selecting the appropriate solvent grades is important since most solvents contain small impurities such as stabilizing chemicals, which will not be detected in UV but will cause interferences in the LC/NMR spectra. Water is usually replaced by D<sub>2</sub>O, which is a relatively 'cheap' deuterated solvent, and gives better quality spectra.

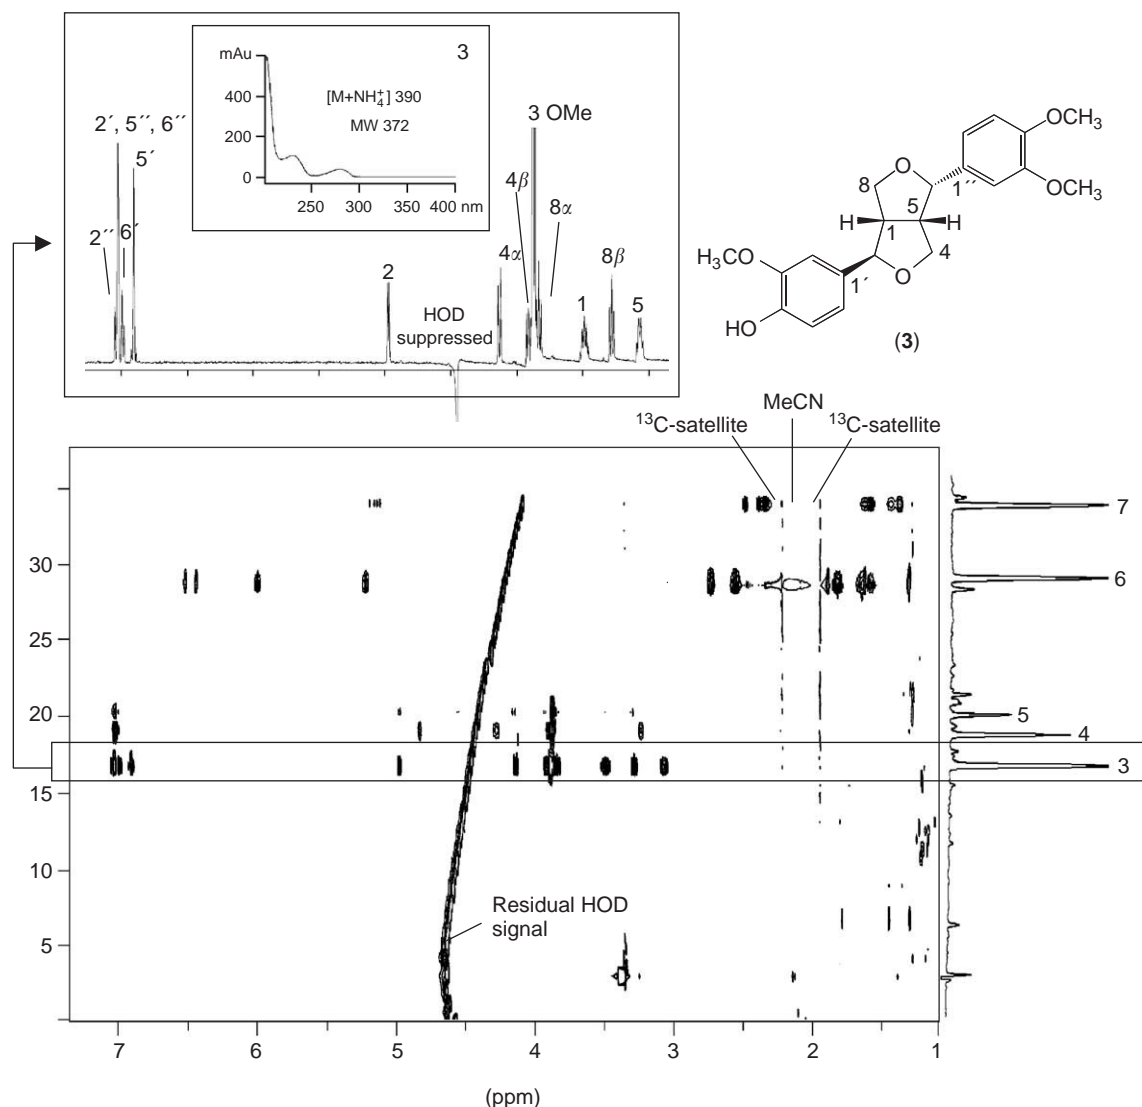

## Gradient Elution

During gradient elution, the frequencies of solvent signals are shifted due to changes of dielectric constants related to the modification of solvent composition. For an effective solvent suppression on-the-fly, a single exploratory scan ('scout scan') is acquired to determine the exact position solvent signals and their suppression is consequently performed by calculation of an adapted selective pulse. The shift of the residual HOD line during gradient elution in the on-flow contour plot of Figure 5 illustrates this phenomenon.

In this case the residual line of MeCN was locked at  $\delta$  2.00.

## Sensitivity

Compared to other analytical techniques (LC/UV or LC/MS), LC/NMR can be regarded as relatively insensitive due to intrinsic properties of NMR detection, which is a consequence of the small energy gap between ground and excited nuclear spin states. On the other hand, limits of detection will also depend on the type of magnet used, LC/NMR applications have been reported on magnets of 400 up to

**Figure 5** On-flow 2D LC/ $^1\text{H}$ -NMR chromatogram of the antioxidant fraction from the  $\text{CH}_2\text{Cl}_2$  extract of *Orophea enneandra* on NovaPak RP-18 ( $150 \times 3.9$  mm i.d.), MeCN- $\text{D}_2\text{O}$  gradient (20:80 to 95:5 in 50 min,  $1 \text{ ml min}^{-1}$ ), 0.05% TFA, 2 mg injected. UV trace was recorded in the same conditions with  $20 \mu\text{g}$  injected. The on-flow spectrum of (–)-phylligenin (3) (NT=32) is displayed. The shift of residual signal of HOD is indicated. LC/NMR conditions: flow cell ( $60 \mu\text{L}$ , 3 mm i.d.), 500 MHz. (Reprinted with permission from Cavin A, Potterat O, Wolfender J-L, Hostettman K, and Dyetmike W (1998) Use of on-flow LC/ $^1\text{H}$  NMR for the study of an antioxidant fraction from *Orophea enneandra* and isolation of a polyacetylene, lignans and a tocopherol derivative. *Journal of Natural Products* 61: 1497–1501; © American Chemical Society.)

900 MHz, and the type of flow probes employed (standard LC/NMR probes: 40–120  $\mu\text{l}$  or microcoils; 20 nl to 1  $\mu\text{l}$ ). The use of new cryo-flow-probes enhances also considerably the sensitivity and a gain of a factor 4 in sensitivity can be roughly obtained compared to noncryogenated systems. Furthermore, the use of new techniques of NMR data acquisition, such as digital filtering and oversampling, also enhance the signal-to-noise ratio (S/N).

The mode of operation also strongly affects sensitivity since in continuous-flow measurements the time of acquisition is limited, while in stop-flow important number of transients can be recorded.

As an example, absolute  $^1\text{H}$ – $^{13}\text{C}$  detection limits of a 100  $\mu\text{l}$  commercially available LC/NMR probe was estimated for 3'-deoxy-3'-azidothymidine (AZT) (MW 252) on a 500 MHz magnet in the stop-flow mode. The S/N ratio of the H'1 proton of the ribose moiety of this molecule was used to define the detection limits. An S/N ratio of 3.0 for this signal was obtained for 1  $\mu\text{g}$  of AZT after 64 scans (5 min) and for 85 ng after an overnight experiment. With 21  $\mu\text{g}$  of AZT, a  $^1\text{H}$ – $^1\text{H}$  2D TOCSY was acquired in 2.6 h and all the cross-peaks of  $^1\text{H}$ – $^{13}\text{C}$  HMQC could be measured overnight. Recently, it was demonstrated that it was possible with a new capillary microcoil probe to detect amounts of  $\alpha$ -pinene as low as 37 ng in the on-flow mode and that detection of an impurity in the subnanomole range was made possible in the stop-flow mode.

## Modes of Operations

Due to the lack of sensitivity, most of the LC/NMR applications requires the accumulation of many transients for achieving a satisfactory detection of the compounds of interest. For the recording of detailed structural information, measurement of 2D correlation experiments is also often mandatory. Consequently, LC/NMR can be operated not only in dynamic but also in static conditions. These main operation modes are described below and require different level of automation:

- on-flow,
- direct stop-flow,
- time-slice,
- loop storage/loop transfer.

### On-Flow Mode

In the on-flow mode, the LC/NMR spectra are acquired continuously during the separation and are stored as a set of scans in discrete increments. The

on-flow data are processed as a 2D NMR experiment. One dimension of the contour plot represents the NMR scale ( $\delta$  ppm) and the other the time scale (min) (Figure 5). According to the analysis, a compromise between the number of scans per increment and the LC resolution has to be made. The main drawback of on-flow LC/NMR is its low sensitivity. In our experience, a rough estimation of the detection limit in the on-flow mode with a 60  $\mu\text{l}$  cell on a 500 MHz instrument was realized for the secoiridoid glycoside swertiamarin (MW 374). An injection of 20  $\mu\text{g}$  of this compound on-column was necessary in order to obtain an S/N ratio of 3 for the olefinic proton H-3 (16 scans/increment 1 ml min<sup>-1</sup>). Thus, practically on-flow LC/NMR measurements will be mainly restricted to the direct measurement of the main constituents of complex mixtures and this often under 'overloaded' LC conditions (typically 1–5 mg of crude mixture injected on-column in the case of crude plant extract analysis).

A simple example of the type of data that can be obtained in the on-flow mode is shown for the online identification of the antioxidant constituents of the  $\text{CH}_2\text{Cl}_2$  extract of an Indonesian medicinal plant *Orophea eneandra* (Annonaceae). This extract had a relatively simple composition consisting of five main constituents. The separation was achieved at 1 ml min<sup>-1</sup> with a MeCN–D<sub>2</sub>O gradient (20:80–95:5 in 50 min). A loading of 2 mg of the extract on-column was necessary and spectra were recorded with 32 transients per increment on a 500 MHz instrument equipped with a 60  $\mu\text{l}$  flow cell. Solvent suppression was performed on-the-fly by applying the WET sequence.

As shown in Figure 5, the LC/ $^1\text{H}$ -NMR spectra were successfully recorded for the five major constituents (3–7) on the LC/NMR contour plot. The important trace starting from 4.8 ppm (at 0 min) and ending at 4 ppm (at 35 min) was due to the change of the chemical shift of the residual negative water (HOD) signal during the LC gradient. The traces around 2 ppm are due to residual  $^{13}\text{C}$  satellite signals of MeCN.

A detailed interpretation of LC/ $^1\text{H}$ -NMR in combination with LC/UV-DAD, LC/MS, and chemotaxonomical data (see the case of 3 in Figure 5) enables the identification of three known lignanes (–)-phylligenin (3), (–)-eudesmin (4), (–)-epieudesmin (5) as well as polycerasoidol (6). Compound (7) could be completely identified based on online data and was finally characterized as a new polyacetylenic natural product named oropheic acid (7). This example also demonstrates the use of LC/UV LC/MS and LC/NMR in phytochemical analysis; known natural products can be dereplicated by comparison

of the spectroscopic information obtained online with literature data and isolation of putative new compounds having particular spectroscopic features can be efficiently targeted.

### Low-Flow Mode, Time-Slice Mode

The detection limits of the on-flow mode can be improved by performing the analysis at low-flow ( $<0.1 \text{ ml min}^{-1}$ ) or by running time-slice experiments over a whole chromatogram. In this latter case, the flow is stopped at defined time intervals. Both modes of operation enable higher number of transients per increments to be recorded and thus a significant improvement in S/N ratio is obtained.

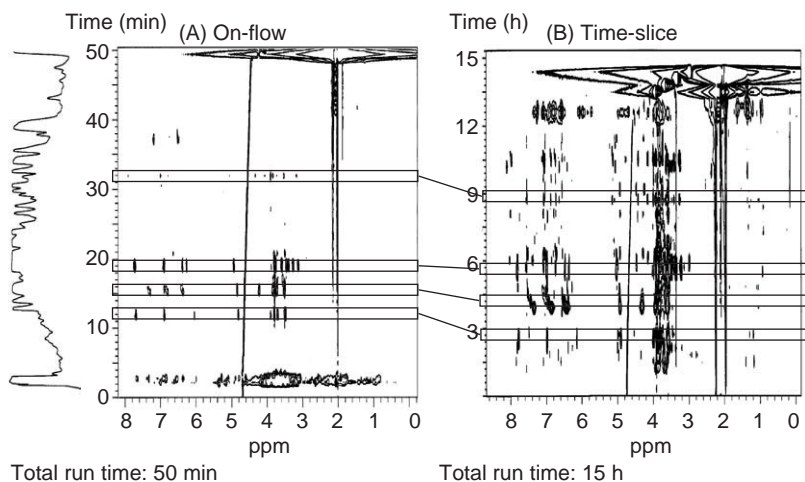

An example of a time-slice experiment on a whole crude plant extract LC chromatogram is shown for the analysis of the constituents of *Gnidia involucrata* (Thymelaceae). As shown in Figure 6, a comparison of the contour plot of the on-flow LC/NMR analysis and the time-slice stop-flow analysis clearly demonstrates the gain in sensitivity that can be obtained in this latter mode. In the on-flow mode (Figure 6A) ( $nt = 24$ , per increment), only the four main constituents of *G. involucrata* were detected but in the time-slice LC/NMR analysis ( $nt = 1024$ ,  $\sim 15 \text{ min}$  acquisition per slice), an important number of minor constituents ( $>20$ ) were revealed (see compounds eluting between 7–12 h in Figure 6B). These different constituents correspond to various xanthone and flavone O- and C-glycosides.

### Stop-Flow Mode

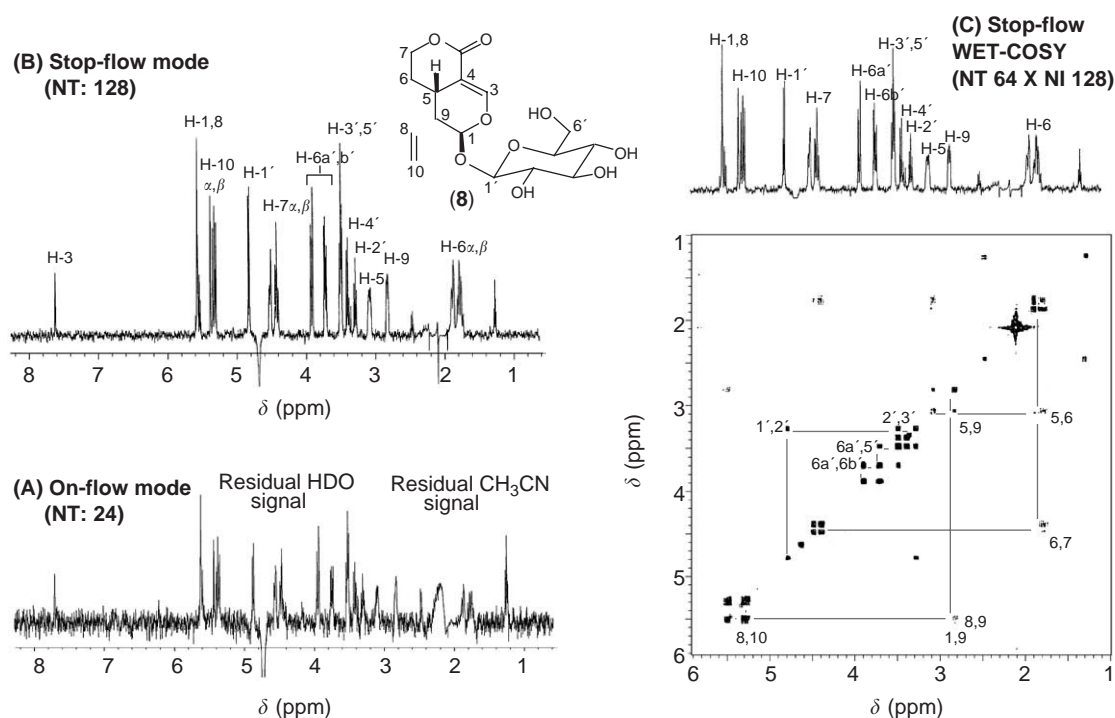

Another way to improve the S/N ratio is the recording of the spectra in stop-flow mode. Operation in the direct stop-flow mode requires that the retention times of the analytes of interest are known or that a sensitive method of detection such as LC/UV or LC/MS is used prior to LC/NMR to trigger the detection. In practice, one of these detectors is connected online before the NMR instrument and the signal of the analytes of interest passing through this detector is used to trigger a valve that will stop the LC flow exactly when the peak reaches the NMR cell after a calibrated delay (for setup, see Figure 2).

The stop-flow mode gives the possibility to acquire an important number of transients on a given LC peak and LC/ $^1\text{H}$ -NMR spectra of compounds present even in the nanogram range can be obtained. An example of the improvement of spectral quality obtained in the stop-flow mode is shown in Figure 7 where the spectra of the bitter principle sweroside (8) recorded in the crude extract of the Gentianaceae *Swertia calycina* in the on-flow and stop-flow modes are compared. The measurement of various 2D correlation experiments such as COSY, NOESY, HSQC, and HMBC is also possible in the stop-flow mode provided that the amount of analyte is high enough. An example of the WET-COSY spectrum recorded for sweroside (8), recorded directly from the crude extract of *S. calycina*, is also shown in Figure 7.

As mentioned earlier, stop-flow can also be operated in the time-slice mode where the flow is

**Figure 6** Comparison of the on-flow and time-slice LC/NMR contour plots of the MeOH extract of the aerial parts of *Gnidia involucrata* (Thymelaceae). As shown, the on-flow experiment allows the detection of four major compounds while the time-slice procedure reveals  $\sim 20$  components. Amount injected: 20 mg. HPLC conditions: C-18 column with radial compression, Waters RCM  $8 \times 10$  ( $100 \times 8 \text{ mm i.d.}$ ); MeCN- $\text{D}_2\text{O}$  gradient (5:95 to 20:80 in 50 min);  $0.9 \text{ ml min}^{-1}$ . LC/NMR conditions: 24 scans/increment (on-flow); 1024 scans/increment (time-slice);  $60 \mu\text{l}$  flow cell ( $3 \text{ mm i.d.}$ ); 500 MHz. (Reproduced with permission from Wolfender J-L, Ndjoko K, and Hostettmann K, (2001) The potential of LC-NMR in phytochemical analysis. *Phytochemical Analysis* 12: 2–22; © John Wiley & Sons Ltd.)

**Figure 7** Comparison of on-flow (A) and stop-flow (B) LC/ $^1\text{H}$ -NMR spectra of sweroside (**8**) in the  $\text{CH}_2\text{Cl}_2$  extract of *Swertia calycina*. (C) WET-COSY spectrum (NT 64  $\times$  NI 128) recorded in the stop-flow mode. LC/NMR conditions: 60  $\mu\text{L}$  flow cell (3 mm i.d.); 500 MHz. automatically stopped at given time intervals through a given peak or on a whole chromatogram. This mode is particularly convenient for analyzing LC peaks that are partially overlapped.

The stop-flow mode can also be operated in a loop storage loop–loop transfer mode. In this case, the LC peaks are stored in a storage device consisting of multiple loops. The analytes are parked in these loops without interrupting the separation. At a later stage the content of the loop is transferred in the LC/NMR flow cell like in the direct stop-flow mode. This process in two steps has the advantage that no disturbance due to the multiple stops in the separation is recorded and that no limitation due to diffusion effects occurs; furthermore, the transfer in the loops is completely independent from the NMR measurements and can be made separately. The mode of operation can be completely automated and different series of NMR experiments can be programmed in advance for each analyte of interest.

### SPE–NMR

The idea of working with LC/NMR at-line, instead of online, gives the possibility to trap the LC/peak of interest on a SPE column installed postcolumn by adding an additional amount of water in the case of typical reversed-phase separations. The SPE cartridge

is dried and the content is transferred into the LC/NMR flow probe with the aid of an appropriate deuterated solvent. This approach enables a preconcentration of the sample of interest on the SPE, multiple trapping are possible, and the S/N ratio is thus enhanced. The separation can be carried out in normal HPLC grade solvents while deuterated solvents are used only to transfer analytes into the NMR probe. This provides ‘cleaner’ spectra without need for solvent suppression.

### Other Coupling

Besides coupling with HPLC, NMR can also be hyphenated with other separation techniques such as gel permeation chromatography (GPC/NMR), supercritical fluid chromatography (SFC/NMR), capillary HPLC (CapLC/NMR), and electrodriven separation techniques such as capillary electrophoresis (CE/NMR).

GPC/NMR coupling opens new opportunities mainly for the characterization of polymers. SFC is very often considered as a niche separation technique mainly for nonpolar analytes. Coupled to NMR, however, SFC/NMR demonstrates the inherent advantage that no solvent suppression is needed and the whole proton chemical shift range can be used

without distortions of solvent signals or impurities. With the development of new NMR flow probes for applications in the microdomains (see above), CapLC/NMR and CE/NMR represents new exciting research fields that enable the characterization of analytes in the nanogram range while carrying separation in fully deuterated solvents.

## Applications of LC/NMR

LC/NMR is now well established and has been integrated in many laboratories often as a complement to LC/UV-DAD and LC/MS for complete characterization of unknown metabolites. Applications of this technique are thus manifold. LC/NMR/MS has demonstrated its potential for many biomedical and pharmaceutical applications and strategies for drug impurities identification, reactivity study, or characterization of mixtures issued from combinatorial chemistry have been described. In drug metabolism studies, applications of LC/NMR are numerous. In this field, LC/NMR was found to be very efficient since structures of the parent drugs are known and precise assignment of the modification occurring after metabolization can be ascertained based on LC/MS and LC/NMR with very good accuracy. In drug metabolism, the use of LC/ $^{19}\text{F}$ -NMR as a very specific detection method for the localization of the metabolites of a fluorinated parent drug was found very efficient since detection of  $^{19}\text{F}$  is much more sensitive than  $^1\text{H}$  in NMR.

LC/NMR in various combinations with LC/UV-DAD, LC/MS, LC/MSMS, LC/IR, and/or LC/CD has been used in many applications related to the online identification of natural products. In this field, the challenge for hyphenated techniques is important since often the characterization of completely unknown molecules is required in very complex biological matrices. In this case, LC hyphenated techniques are used for the chemical evaluation of biologically active fractions or extracts and for de-replication purposes. As full structure assignment is often needed, all online spectroscopic data are taken into consideration. Most applications are performed in the stop-flow mode and extensive 2D NMR correlation experiments are measured. For unknown online determination the need for  $^{13}\text{C}$  data is often mandatory. This type of information can be deduced from HSQC and HMBC indirect measurements and very recently it has been demonstrated that even direct  $^{13}\text{C}$  measurements were possible in a crude plant extract. For this application the LC peak of interest was preconcentrated by trapping on SPE and the measurement was performed on a cryogenic flow

probe. In this field, LC/NMR has also revealed to be very useful for the structural assignment of unstable natural products or compounds not isolable at the preparative scale.

Different applications of LC/NMR in environmental problems have also demonstrated the interest of the approach for nontarget analysis of organic compounds in the samples. On the basis of the LC/NMR and LC-MS, a screening of various pollutants can be performed and target analysis of specific pollutants can be efficiently developed in a second step with more sensitive methods for a definitive identification.

As shown in this section, LC/NMR has been used successfully in various field of analytical chemistry. Further optimizations of the technique are, however, still awaited, especially on sensitivity issues. Very recently impressive progress, particularly with the introduction of liquid helium cooled cryoprobes and flow probes solenoid coils designs, has already improved considerably the detection limits.

LC/NMR is often used within multi-hyphenated systems in different fields of application, especially LC/NMR/MS. In this case, MS is used as an efficient and selective detection method to trigger NMR experiments only on the peaks of interest, which render the targeted measurement extremely valuable.

LC/NMR is probably still not mature for real demanding high throughput studies, but it is a safe bet to say that, considering the very recent development recorded, this powerful tool will play a major role in many aspects of analytical chemistry where the identification of LC peaks is mandatory.

### Introduction

The first approach to automatic liquid chromatography (LC) of amino acids (AAs) – known today as ion-exchange chromatography – was published by Spackman, Stein, and Moore in 1958, which led to the award of the Nobel Prize in 1972 to Stanford Moore and William H. Stein. Forty-five years later, it now takes less than 5 min (**Figure 1**) to separate and quantitate the essential protein AAs instead of 2 days. Early separations were carried out by postcolumn derivatizations.

Over the last 20 years, LC has offered unlimited possibilities in both preparative and analytical scales. The wide range of sophisticated columns, detectors, derivatization procedures, modern instrumentation, and data handling systems reduce operating time and costs, and give versatility and automation in Good Laboratory Practice conditions for selectivity, sensitivity, and reproducibility. It is the responsibility of the researcher to choose the most appropriate method for a given task. The most popular LC method for analysis of both free AAs (present in many natural matrices, biological fluids, and tissues, feedstuffs, and foodstuffs) and of constituents of protein hydrolysates is now reverse-phase (RP) chromatography after precolumn derivatization of the AAs. Numerous methods are available for derivatization.

### Introduction

The first approach to automatic liquid chromatography (LC) of amino acids (AAs) – known today as ion-exchange chromatography – was published by Spackman, Stein, and Moore in 1958, which led to the award of the Nobel Prize in 1972 to Stanford Moore and William H. Stein. Forty-five years later, it now takes less than 5 min (**Figure 1**) to separate and quantitate the essential protein AAs instead of 2 days. Early separations were carried out by postcolumn derivatizations.

Over the last 20 years, LC has offered unlimited possibilities in both preparative and analytical scales. The wide range of sophisticated columns, detectors, derivatization procedures, modern instrumentation, and data handling systems reduce operating time and costs, and give versatility and automation in Good Laboratory Practice conditions for selectivity, sensitivity, and reproducibility. It is the responsibility of the researcher to choose the most appropriate method for a given task. The most popular LC method for analysis of both free AAs (present in many natural matrices, biological fluids, and tissues, feedstuffs, and foodstuffs) and of constituents of protein hydrolysates is now reverse-phase (RP) chromatography after precolumn derivatization of the AAs. Numerous methods are available for derivatization.

**Figure 1** Separation of the phenylthiocarbamyl (PTC) AAs separated on TSKgel Super-ODS (details in **Table 3**), peaks: 1 = Asp, 2 = Glu, 3 = Ser, 4 = Gly, 5 = His, 6 = Arg, 7 = Thr, 8 = Ala, 9 = Pro, 10 =  $\text{NH}_4^+$ , 11 = Tyr, 12 = Val, 13 = Met, 14 = Cys, 15 = Ile, 16 = Leu, 17 = Phe, 18 = Lys. (Reproduced with permission from Catalogue (2003) *TosoHaas Biosciences*, p. 16.)

In this article, special emphasis is placed (1) on the recently developed detector systems that have opened a new perspective/area for the direct quantitation of AAs in their underivatized form, and (2) on the elucidation of the background and contradictions of the most commonly used and popular *o*-phthaldialdehyde (OPA) derivatization method.

Current trends in AA analysis identify the best conditions for the separation of enantiomers and the development of LC-mass spectrometry (LC-MS, LC-MS/MS), detailed elsewhere.

## LC of Underivatized AAs

One of the main advantages of LC, which has appealed to chromatographers, is the separation of the 'classical 20' as underivatized AAs. In spite of a number of efforts using both earlier methods (indirect ultraviolet (UV) or fluorescence (FL) detection, *in situ* complexation with Cu(II), and electrochemical detections) and those using recent methods, which apply special detections (chemiluminescence nitrogen detector (CLNSD), ELSD, MS, MS-MS), the simultaneous LC of underivatized AAs has remained of secondary importance so far. The determination of a few selected AAs, such as tryptophan or sulfur-containing AAs, has proved to be significant for special tasks.

The aim of various investigations has been to render the time-consuming derivatization techniques unnecessary. However, the characteristics of the free AAs are considerably different from each other and their various structural properties have not permitted their easy resolution. Thus, in attempting to achieve better separation of free AAs, further means of discriminations are needed. For this purpose special techniques have been introduced, such as the use of various phase systems, ion pairs, and ligand-exchange chromatography, column-switching techniques, or anion-exchange chromatography with electrochemical detection.

Recently, a comprehensive work was published that applied uniform experimental conditions, providing a basis for comparison and critical evaluation of the state of the art of detection (not quantitation) of AAs in their underivatized form. Based on the comparison of seven different detection systems under the same chromatographic conditions, the following conclusions could be drawn: due to the intrinsic specificity of these detection systems, in order of listing, they ensured increasing selectivity associated with increasing sensitivity (characterized with the limit of detection (LOD) as follows: refractive index detection:  $\text{LOD} = 50 \text{ mg l}^{-1}$ ; indirect

conductivity:  $\text{LOD} = 1\text{--}25 \text{ mg l}^{-1}$  or  $11^{-1}$ ; chemiluminescence nitrogen:  $\text{LOD} = 0.33\text{--}0.7 \text{ mg l}^{-1}$ ; MS:  $\text{LOD} = 0.2\text{--}5 \text{ mg l}^{-1}$ ; tandem mass spectrometric, MS-MS:  $\text{LOD} = 50.08\text{--}0.8 \text{ mg l}^{-1}$ ) during detections.

For tryptophan and the sulfur-containing AAs (cysteine/cystine, methionine, glutathione, etc.), the fast isocratic elution of the underivatized samples has gained wide acceptance and is a powerful tool in their quantitation.

Tryptophan can be measured directly, within 8 min, in neutralized alkaline hydrolysates of feed- and foodstuffs, using an RP column, 5% methanol containing acetate buffer ( $\text{pH} \sim 4.0$ ) and UV detection (280 nm). The pulsed amperometric detection of sulfur-containing AAs, at the low picomole level, was carried out with an Au working electrode and an Ag/AgCl reference electrode, subsequent to their separation on both cation-exchange and RP columns, applying as mobile phase  $0.1 \text{ mol l}^{-1} \text{ HClO}_4/0.15 \text{ mol l}^{-1} \text{ NaClO}_4/5\% \text{ acetonitrile}$ .

## LC of Derivatized AAs

Derivatization studies have concerned the optimization of parameters, such as the yield and stability of derivatives, to separate and quantitate all AAs with a simple and fast elution procedure.

### Postcolumn Derivatization

Drawbacks of the postcolumn techniques (Table 1) are long elution times and the need of expensive devices, such as a delivery system for the derivatizing reagent (one or more extra pumps): (1) mixing chamber for the column effluent and the reagent(s); (2) special thermostable reactors (packed bed, air segmented, and/or coir reactors) ensuring the necessary delay for quantitative reactions accompanied with as small band broadening as possible; (3) finally, the mobile phase was probably incompatible with the derivatizing reagent. The preferred mobile phase might be inappropriate for the optimum conditions of the derivatization reaction. The early and current stage of postcolumn methods can be illustrated by the elution followed by postcolumn reaction with ninhydrin (NHYD; Figure 2A), with *o*-phthaldialdehyde/2-mercaptoethanol (OPA/MCE; Figure 2B), or with 1,2-naphthoquinone-4-sulfonyl chloride (NQS; Figure 2C). All three types of derivatives have been separated in most cases on ion-exchange resin columns. Recent postcolumn methods are, without exception, slow separations (Table 1). However, the efficiency of the recently published methods of NHYD derivatives using short columns proved to

be superior, determining 99 compounds in 150 min (Figure 2A).

### Precolumn Derivatization

Precolumn derivatization offers numerous advantages (Tables 2 and 3, Figures 3–6). It requires less equipment and allows the evaluation of the derivatives in an easier way from the point of view of their selectivity, sensitivity, various means of detection, derivatization yield, stability, and storability. All of these phenomena can be controlled and improved by means of modern instrumental techniques and computerization, both individually and simultaneously. Potential disadvantages in precolumn derivatization procedures can be completely avoided, such as contamination from the reagents (due to their insufficient purity) and loss of analyte from incomplete interactions, undesirable side reactions, and sample handling losses.

Although numerous precolumn derivatization techniques have been introduced in the last 35 years, none complies with the criteria of an ideal procedure: providing rapid and quantitative interaction in aqueous media, permitting mild conditions, ensuring interaction with both primary and secondary AAs, and resulting in single and stable derivatives in the case of all AAs.

### OPA Derivatives

The pioneering work of Roth (1971) on the very fast reaction of AAs in aqueous solutions with OPA/MCE detectable by both UV and FL, without the need to remove excess reagent, represented a great advance (Table 2, Figure 3).

Because of the different and low stability of the isoindoles obtained from the reaction of AAs with OPA/MCE reagent, alternative precolumn derivatizations reagents, such as 3-mercaptopropionic acid (MPA) and several *N*-alkyl-L/D-cysteines, were proposed. The OPA/MPA and OPA/*N*-acetyl-L-cysteine (NAC) reagents provide more stable isoindoles compared to those formed with the OPA/MCE, and the optical resolution of enantiomeric AAs with the OPA/NAC, as well as with further *N*-alkyl-L/D-cysteine reagents, have opened a new area in separation of AA enantiomers. Due to robotic auto-samplers, which provide excellent reproducibility even for moderately quantitative interactions, most AA analyses are performed with the OPA derivative. The unexplainable contradictions of this most popular process – relating to the particularly low stability of the OPA derivatives of six very important AAs (glycine,  $\gamma$ -aminobutyric acid (GABA),  $\beta$ -alanine,

histidine, ornithine, and lysine) – have recently been studied and clarified by following two approaches.

First, stoichiometric investigations – based on simultaneous photodiode array (PDA) and FL detections – revealed that the above-selected AAs provided more than one OPA derivative. Thus, taking into account that their initially formed derivatives are transformed, these six AAs provide acceptable stability: to achieve their reproducible quantitation with the same molar responses as other AAs, only a proper elution protocol is needed and they can be quantitated on the basis of the total on their derivatives (Figures 3A and 3B).

Second, structure of the transformed OPA derivatives (containing two OPA molecules) and the reaction mechanism leading to the transformation are determined by online high-performance liquid chromatography (HPLC)–UV–MS evidences. It has been confirmed that the common characteristics of the presumably less stable OPA derivatives are associated with their original molecular structure: they contain the  $\text{NH}_2\text{--CH}_2\text{--R}$  moiety, and all of them furnish more than one OPA derivative. In the light of the common structure of the multiple OPA derivatives providing compounds, a plausible reaction pathway has been introduced, fully supported by

**Figure 2** Continued

MS fragmentation patterns of all; in their initial structure the  $\text{NH}_2\text{-CH}_2\text{-R}$  moiety containing primary amino compounds.

The essential shortage of an OPA/S<sub>H</sub> group reagent (reactive toward primary AAs only) can be eliminated by Shuster's principle – the automatic two-step precolumn derivatization method – by applying the OPA/MPA/fluorenylmethyl-chloroformate

(FMOC) reagent, which also ensures derivatization of the secondary AAs. A high-speed elution of OPA/MPA/FMOC derivatives has been observed recently (Table 2, Figure 3B: 19 compounds/8 min). In the new improved methods, shorter, thermostated columns of smaller particle size with autosamplers are used, which provide greater sensitivity and reproducibility.

### Phenylthiocarbamyl, FMOC, 1-*N,N'*-Dimethylaminonaphthalene-5-sulfonyl, and Dimethylaminoazobenzenesulfonyl Derivatives

Judging by the number of publications in the last decade, the interest in Phenylthiocarbamyl (PTC) and FMOC derivatives has proved to be lasting, that in OPA derivatives is increasing, while the application of Dimethylaminonaphthalene-5-sulfonyl (DANS) and Dimethylaminoazobenzenesulfonyl (DABS) derivatives is decreasing. However, in the direct enantiomer separation of AAs, the use of the DANS derivatives is preferred.

The reaction of AAs with phenylisothiocyanate (Table 3, Figures 1, 4, 5), in water-free media and at ambient temperature, is quantitative and fast (10 min), resulting in the highly stable single PTC derivatives (except for cyst(e)ines in hydrolysates that elute in one to four peaks). The excess of the reagent is removed by vacuum, and the PTC derivatives can be stored in the freezer for long periods of time, and for a day after dissolution in buffer at 4°C. UV detection at 254 nm allows their quantitation. The short TSK gel (Figure 1) and the short PicoTag (Figure 4) column can separate 17 AAs within 4.5 and 12 min, respectively, while applying a multistep gradient provides the separation of 27 AAs, including the hardly separable GABA, histidine, threonine, alanine, and ACPA (Figure 5).

The first LC separation of the strongly fluorescent DANS AAs has been used earlier in protein chemistry and in thin-layer chromatography. The decreased popularity of this technique in LC can be explained by its main disadvantages: long reaction times, elevated temperatures for derivatization, generation of FL side products (DANS hydroxide, DANS amide), and interference from excess reagent. The disturbing effect of these compounds cannot be completely eliminated, and they elute between the AA derivatives. No significant improvement has been obtained and is not expected. DABS AAs were first separated by applying precolumn labeling. Derivatization was performed using Na<sub>2</sub>CO<sub>3</sub>/NaHCO<sub>3</sub> buffer, at pH ~8.9, with DABS chloride dissolved in acetone under continuous stirring at 80°C for 10 min. DABS AAs can be stored for 4 weeks in solution at 25°C, without any changes. In spite of the unique stability of DABS AAs in aqueous media and the improvement in their chromatographic conditions, the use of the DABS AAs is dwindling.

FMOC was introduced in 1983 as a fluorescent labeling agent, reacting rapidly with both primary and secondary AAs under mild conditions (borate buffer, pH 7.7–8.0) to give stable derivatives. The excess reagent is extracted by pentane. Recent derivatization studies have shown that, depending

on the time (2 and 40 min) and pH (8.0 and 11.4), considerable differences can be found. At pH  $\sim 8$  acidic AAs manifest low responses, and a slow reaction was experienced; histidine and tyrosine yield their mono- and disubstituted derivatives in varying ratios. With longer reaction times, the amount of disubstituted histidine decreases and that of tyrosine increases, together with interfering hydrolysis products of the reagent. At pH  $\sim 11.4$ , faster reaction and less interfering hydrolysis products were found. After 40 min reaction time, the monosubstituted histidine

and the disubstituted tyrosine are formed in quantitative yield. Also, 30% less hydrolysis product was obtained, favoring the resolution of the neighboring alanine. The separation of the Fmoc derivatives and the presence of interfering substances are shown in Figure 6.

## Chiral Analysis of Amino Acids

### Introduction

Methods for the chiral separation of amino acids can be divided into two categories: one is an indirect method based on the formation of diastereomers by the reaction of amino acids with a chiral derivatization reagent and separation of the diastereomeric derivatives on an achiral stationary phase. The other is a direct method based on the formation of diastereomers on a stationary phase or in a mobile phase, where the former uses a chiral stationary phase (CSP) and the latter adds a chiral selector in a mobile phase and uses an achiral stationary phase.

The indirect method is an efficient technique for the enantioseparation of amino acids. However, it is essential that the chiral derivatization reaction proceeds completely in both enantiomers, and that the racemization reaction does not occur. Furthermore, if the optical purity of the derivatization reagent is not known, and/or is not taken into consideration, the optical purity of the amino acid will not be determined precisely. Thus, the indirect method is unsuitable for the analysis of amino acid enantiomers in a standard sample and pharmaceutical preparations, where a low amount of antipode, at a level of 0.1 or 0.05%, should be determined.

Furthermore, it is also unsuitable for preparative purposes. However, it is suitable for the trace analysis of amino acid enantiomers in complex matrices such as biological samples because of the introduction of a highly sensitive ultraviolet-visible or fluorescence tag.

The direct method based on CSPs is divided into two categories: one is the direct enantioseparation of underivatized amino acids on a CSP and the other is the enantioseparation on a CSP following derivatization with an achiral reagent (**Figure 1**). At present, both methods are complementarily used for the enantioseparation of amino acids by liquid chromatography. The direct method, using a CSP, is suitable for the analysis of underivatized amino acid enantiomers in a standard sample and pharmaceutical preparations, where low amounts of the antipode should be determined. Furthermore, it is suitable for preparative purposes. For trace analysis of the amino acid enantiomers, especially D-forms, in complex matrices such as biological samples, derivatization with an achiral reagent combined with liquid-liquid extraction, solid-phase extraction, or column switching technique is followed by the enantioseparation on a CSP. However, in this case it is important that the derivatization reaction proceeds completely in both enantiomers and that the racemization reaction does not occur. On the other hand, the direct method using chiral mobile phase additives has the same drawback with regard to the optical purity of chiral selectors. This article deals with two chiral separation methods of amino

**Figure 1** Achiral derivatization reagents used for the derivatization of amino acids followed by the enantioseparation on chiral stationary phases.

acid enantiomers by liquid chromatography: indirect and direct methods.

## Indirect Method

Many chiral derivatization reagents have been developed for the enantioseparation of amino acids wherein ultraviolet-visible or fluorescence tags are introduced. The fluorescence derivatization is more effective for the determination of amino acid enantiomers in complex matrices in terms of sensitivity and/or selectivity. **Table 1** shows the chiral derivatization reagents, whose structures are shown in **Figure 2**, used for the enantioseparation of amino acids.

Amino acids have two functional groups, amino and carboxylic acid groups, which react with chiral derivatization reagents. Many chiral derivatization reagents that react with primary and/or secondary amino groups have been developed. It is well known that primary amino acids react with *o*-phthalaldehyde (OPA) in the presence of an achiral sulfhydryl reagent such as 2-mercaptoethanol or ethanethiol and yield the fluorescent products. The reaction of amino acids with a chiral sulfhydryl reagent such as *N*-acetyl-L-cysteine, *N*-butyloxycarbonyl-L-cysteine, *N*-acetyl-D-penicillamine, or 2,3,4,6-tetra-*O*-acetyl-1-thio- $\beta$ -glucopyranoside, instead of the achiral sulfhydryl reagent gives the corresponding diastereomeric amino acids, which are separated on an achiral, C8, or C18 column. The disadvantage of this reagent is that the secondary amino acids do not react and that the reaction products have limited stability. On the other hand, the reaction of 1-(9-fluorenyl)ethyl chloroformate (FLEC) with primary and secondary amino acids gives stable fluorescent products at room temperature within 4 min. **Figure 3**

shows the enantioseparation of 17 primary amino acids derivatized with FLEC on a C18 column, where a linear gradient with tetrahydrofuran is employed to facilitate the separation of derivatized asparagine and glutamine.

Many chiral derivatization reagents based on an isothiocyanate group have been developed for the enantioseparation of primary and secondary amino acids. These include 2,3,4,6-tetra-*O*-acetyl- $\beta$ -D-glucopyranosyl-isothiocyanate (GITC), 4-(3-isothiocyanatopyrrolidin-1-yl)-7-nitro-2,1,3-benzoxadiazole (NBD-PyNCS), 4-(3-isothiocyanatopyrrolidin-1-yl)-7-(*N,N*-dimethylaminosulfonyl)-2,1,3-benzoxadiazole (DBD-PyNCS), 1,3-diacetoxy-1-(4-nitrophenyl)-2-propylisothiocyanate (DANI), and *N*-[(2-isothiocyanato)cyclohexyl]-6-methoxy-4-quinolinylamide (CDITC). The derivatization of amino acids with the corresponding isothiocyanates yielded highly fluorescent thioureas. These derivatives were separated on an achiral C18 column.

The chiral derivatization reagents bearing an amino group include 1-(4-dimethylamino-1-naphthyl)ethylamine (DANE), 4-(3-aminopyrrolidin-1-yl)-7-nitro-2,1,3-benzoxadiazole (NBD-APy), and 4-(3-aminopyrrolidin-1-yl)-7-(*N,N*-dimethylaminosulfonyl)-2,1,3-benzoxadiazole (DBD-APy). The derivatization of amino acids with these reagents yielded the corresponding amide derivatives, and the diastereomeric amide derivatives produced were separated by normal or reversed-phase chromatography.

## Direct Method

### Chiral Stationary Phases

The CSPs based on aromatic  $\pi$ -acid (3,5-dinitrobenzene) and  $\pi$ -base ( $\alpha$ -naphthalene moiety) derivatives are called Pirkle-type stationary phases. These CSPs cannot separate underivatized amino acid enantiomers. However, after derivatization of amino acids with a fluorogenic benzofurazan reagent such as 4-fluoro-7-nitro-2,1,3-benzoxadiazole (NBD-F), 4-(*N,N*-dimethylaminosulfonyl)-7-fluoro-2,1,3-benzoxadiazole (DBD-F), or 4-aminosulfonyl-7-fluoro-2,1,3-benzoxadiazole (ABD-F), the resulting products were separated on Pirkle-type stationary phases in normal or reversed-phase mode. D-Amino acids in biological samples were determined by derivatization with NBD-F, enantioseparation and fluorometric detection following deproteinization of serum or brain homogenates with methanol. Also, column switching techniques using C18 and Pirkle-type columns were developed for the determination of D-amino acids in biological fluids. The former was used for the separation of the individual amino acids

**Table 1** Chiral derivatization reagents used for the enantioseparation of amino acids

DBD-Apy	NH <sub>2</sub>	Reversed phase

**Figure 2** Chiral derivatization reagents used for the enantioseparation of amino acids.

derivatized with NBD-F, while the latter for the enantioseparation of the respective amino acid derivatives. Furthermore, 3,5-dinitrobenzoyl- or 3,5-dinitroanilido-amino acids were separated on Pirkle-type CSPs. In Pirkle-type CSPs, in addition to

$\pi$ - $\pi$  interactions, hydrogen bonding and/or dipole-dipole interactions could help in chiral recognition of amino acid derivatives.

CSPs based on carbamoylated derivatives of quinine and quinidine as chiral selectors were found

**Figure 3** Separation of a standard solution of D- and L-amino acids by chiral derivatization with (+)-1-(9-fluorenyl)ethyl chloroformate followed by high-performance liquid chromatography on an achiral column. Column: Spherisorb octyl material (150 × 4.6 mm). Mobile phase: acetonitrile (ACN), tetrahydrofuran (THF), and an acetic acid buffer (1.8 ml of glacial acetic acid in 1 l of water; pH adjusted to 4.35 with NaOH): Gradient: 0–8 min, 8% ACN, 17% THF, 75% buffer (8/17/75); 8–22 min, 8/17/75 to 0/30/70; 22–70 min, 0/30/70 to 0/50/50. Flow rate: 0.8 ml min<sup>-1</sup>. (Reprinted with permission from Einarsson S, Josefsson B, Möller P, and Sanchez D (1987) *Analytical Chemistry* 59: 1194; © American Chemical Society.)

to be highly enantioselective for *N*-derivatized amino acids. Since carbamoylated quinine or quinidine has a positive charge, ionic interactions between the positively charged selectors and negatively charged amino acid enantiomers could work for chiral recognition of *N*-derivatized amino acids.

Recently, CSPs based on macrocyclic antibiotics such as vancomycin, teicoplanin, or ristocetin A have been introduced. These CSPs can separate many enantiomers of underivatized and derivatized amino acids in the normal and reversed-phase modes. In addition to  $\pi$ - $\pi$  interactions, hydrogen bonding, electrostatic and hydrophobic (in the case of reversed-phase mode) interactions could help in the chiral recognition of amino acid derivatives.

Cellulose and amylose derivatives are the best chiral selectors for the enantioseparation of various compounds. However, tris(3,5-dimethylcarbamate)s of cellulose and amylose only showed high resolving power for *N*-benzyloxycarbonyl  $\alpha$ -amino acid esters.

Crown ethers are synthetic macrocyclic polyethers that can form selective complexes with various cations. Chiral crown ethers such as (diphenyl-substituted 1,1'-binaphthyl) crown ether or (+)-(18-crown-6)-2,3,11,12-tetracarboxylic acid, which are bound to silica gels or coated on reversed-phase materials, were utilized for the enantioseparation of underivatized primary amino acids and their esters. On the other hand, the enantiomers of underivatized and derivatized amino acids enter into

hydrophobic chiral cavities of cyclodextrins (CDs) to form inclusion complexes, and relative stability constants of the resulting diastereomeric complexes are different. Underivatized amino acids such as tryptophan, phenylalanine, tyrosine, and their analogs can be separated on  $\alpha$ -CD bonded stationary phases using aqueous or hydro-organic mobile phases. However, other CDs ( $\beta$ - and  $\gamma$ -CDs) cannot separate underivatized amino acids. Amino acids derivatized with phenylisothiocyanate (PITC), OPA, dansyl chloride (DNS-Cl), or 9-fluorenylmethyl chloroformate (FMOCl) were separated on underivatized CDs ( $\alpha$ -,  $\beta$ -, and  $\gamma$ -CDs), and derivatized CDs (naphthylethyl carbamoylated and amino CDs). The enantioseparation of phenylthiocarbonyl derivatives of amino acids (amino acids derivatized with PITC) was attained on a series of reversed-phase HPLC columns and derivatized  $\beta$ -CD columns. **Figure 4** shows a chromatogram of the separation of 37 phenylthiocarbonyl amino acids on octyl and phenylcarbamoylated  $\beta$ -CD columns coupled in series. As described above, the former was used for the separation of the individual amino acids derivatized with PITC and the latter for the enantioseparation of the respective amino acid derivatives.

Chiral ligand-exchange chromatography is based on the formation of diastereomeric ternary complexes that involve a transition metal ion, chiral ligand, and the amino acid enantiomers. Among transition metals, Cu(II) formed the most stable complexes

**Figure 4** Separation of a mixture of 37 phenylthiocarbamoyl amino acids by achiral derivatization followed by high-performance liquid chromatography on a chiral stationary phase (second column). Column and temperature: Octyl-80Ts ( $150 \times 4.6$  mm) and phenylcarbamoylated  $\beta$ -CD ( $150 \times 6.0$  mm) columns were coupled in series at column temperatures of 30 and 20°C, respectively. Mobile phase: (A)  $100 \text{ mmol l}^{-1}$  ammonium acetate (pH 6.5) containing  $1 \text{ mmol l}^{-1}$  sodium butanesulfonate; (B)  $100 \text{ mmol l}^{-1}$  ammonium acetate (pH 6.5)/methanol = 50/50 (v/v) containing  $1 \text{ mmol l}^{-1}$  sodium butanesulfonate. Gradient: isocratic elution until 50 min (B, 0%), linear gradient elution from 50 to 80 min (B, 0–20%), then from 80 to 110 min (B, 20–80%), isocratic elution from 110 to 150 min (B, 80%). when cyclic amino acids such as L-proline and L-4-hydroxyproline were used as the ligand. For chiral ligand-exchange chromatography of amino acids, chemically bound L-proline, L-4-hydroxyproline,

D-penicillamine, L-phenylalanine amide, L-alanine amide, or L-proline amide to silica gels or polymers was used as a CSP, and Cu(II) ion was added in a mobile phase, or adsorbed on the CSP. The

enantioseparation of underivatized amino acids and derivatized amino acids (dansyl amino acids or *N*-methyl amino acids) was attained.

Many CSPs based on a protein have been developed. CSPs based on bovine serum albumin or human serum albumin could be only utilized for the enantioseparation of underivatized tryptophan, while other underivatized amino acids were not enantioseparated. However, they can separate derivatized amino acids such as dansylated ones. A CSP based on  $\alpha$ -chymotrypsin and trypsin could be used for the enantioseparation of underivatized amino acid (tryptophan, arginine, or histidine), and *N*- or *O*-derivatized amino acids. Ovomucoid-based CSP could separate only derivatized amino acids. Recently, antibodies against protein conjugates of *D*- and *L*-*p*-aminophenylalanine were prepared, and applied to the enantioseparation of racemic amino acids such as phenylalanine, tryptophan, tyrosine, and histidine. The antibodies only recognized  $\alpha$ -amino acids that have the correct configuration; i.e., anti-*D*-amino acid antibodies bound to *D*-amino acids and anti-*L*-amino acid antibodies bound to *L*-amino acids. Chiral recognition mechanisms of protein CSPs are based on combinations of hydrophobic, electrostatic, and hydrogen bonding interactions. The disadvantages of these CSPs are low column efficiency because of too strong interactions of CSPs and enantiomers, especially late eluted ones, and lack of repetitive usage of the column.

In the molecular imprinting technique, a template molecule is polymerized in the presence of a functional monomer, which interacts with the template molecule. Thus, the obtained molecularly imprinted polymers (MIPs) could be used for the specific recognition of the template molecule. The MIPs for *N*- or *O*-derivatized amino acid enantiomers were prepared using methacrylic acid (MAA) as a functional monomer and ethylene glycol dimethacrylate as a crosslinker. The enantiomer used as the template molecule was strongly recognized on the obtained MIPs, and eluted latter than the antipode. With regard to enantiomeric resolution of underivatized amino acids, a ligand-exchange MIP based on the MAA-derivatized silica for *D*-phenylalanine was prepared using Cu(II)-*N*-(4-vinylbenzyl)iminodiacetic acid as an achiral monomer. The MIP obtained could separate racemic phenylalanine and tyrosine, but could not resolve racemic tryptophan, alanine, leucine, and isoleucine. The chiral recognition mechanism could be explained as follows: re-binding of the *D*-enantiomer proceeds through chelation of the metal ion, in addition to which the aromatic side chain fits into a cavity that selects for both the size and shape of this group, as shown in

Figure 5A. In contrast, metal chelation by the *L*-enantiomer would be sterically hindered (Figure 5B). If the side group of the *L*-enantiomer fits into the cavity, binding to the metal would be obstructed (Figure 5C). Racemic tryptophan and aliphatic

**Figure 6** Effect of chirality of the mobile phase additives on the separation of *D*- and *L*-amino acid enantiomers by ligand-exchange chromatography. Column: DC 4a cation-exchange resin ( $12 \times 0.2$  cm). Mobile phase: sodium acetate buffer ( $0.05 \text{ mol l}^{-1}$ , pH 5.5) containing  $4 \times 10^{-3} \text{ mol l}^{-1} \text{ CuSO}_4$  and  $8 \times 10^{-3} \text{ mol l}^{-1}$  proline. amino acids could not be resolved on the MIP because of the loose fit into the cavity.

### Chiral Mobile Phase Additives

There are no fundamental differences between the techniques using CSPs and chiral mobile phase additives. This means that all chiral selectors covalently bound to or coated on supports can be used for the enantioseparation of amino acids by addition to the mobile phase.

The most frequently used additives in chiral ligand-exchange chromatography are Cu(II) complexes of chiral ligands such as D- or L-proline, esters of L-proline or L-arginine,  $N^2$ -octyl-(S)-phenylalaninamide, or *N*-(*p*-toluenesulfonyl)-L-phenylalanine. Underivatized amino acids, amino acid amides, amino acid esters, and dansyl amino acids were separated using achiral C18 or ion-exchange columns. **Figure 6** shows the effect of the chiral ligand on the enantioseparation of underivatized amino acids. When a Cu(II) complex of L-proline ligand was used as the mobile phase additive, the L-enantiomers of amino acids eluted before the corresponding D-enantiomers (**Figure 6A**). When the antipode was used as the ligand, the elution order was reversed (**Figure 6B**). Furthermore, no enantiomeric resolution of amino acids was observed with a racemic Cu(II)-proline complex (**Figure 6C**).

CDs or derivatized CDs were used for the enantioseparation of dansyl- or *t*-butyloxycarbonyl-amino acids as the chiral mobile phase additive. One macrocyclic antibiotic, LY33328, was used for the enantioseparation of nine dansyl amino acids.

### Introduction

Biotechnology, i.e., the development and application of expertise from the disciplines of biology, chemistry, and engineering, represents a rapidly growing modern industry, which is increasingly being considered an important driving factor in many of today's economies. The spectrum of biotechnological products covers a wide range from simple substances such as ethanol and citric acid through antibiotics and vaccines to the most advanced 'biopharmaceuticals'

such as recombinant proteins, antibodies, or DNA-based therapeutics. Concomitantly a wide range of production organisms and conditions are used by the industry, while the application spectrum of 'biotechnology' covers areas as diverse as agriculture, food science, general industry, and, perhaps most importantly, medicine.

However, there are certain common motifs in analytical biotechnology, which is mainly focused on process monitoring and control on the one side and quality control (identity, purity, stability) of the final product on the other. Monitoring the downstream process, i.e., product isolation and purification, then combines aspects of both areas. Analytical biotechnology has to operate within rather strict boundaries. In particular, the most precious

amino acids could not be resolved on the MIP because of the loose fit into the cavity.

### Chiral Mobile Phase Additives

There are no fundamental differences between the techniques using CSPs and chiral mobile phase additives. This means that all chiral selectors covalently bound to or coated on supports can be used for the enantioseparation of amino acids by addition to the mobile phase.

The most frequently used additives in chiral ligand-exchange chromatography are Cu(II) complexes of chiral ligands such as D- or L-proline, esters of L-proline or L-arginine,  $N^2$ -octyl-(S)-phenylalaninamide, or *N*-(*p*-toluenesulfonyl)-L-phenylalanine. Underivatized amino acids, amino acid amides, amino acid esters, and dansyl amino acids were separated using achiral C18 or ion-exchange columns. **Figure 6** shows the effect of the chiral ligand on the enantioseparation of underivatized amino acids. When a Cu(II) complex of L-proline ligand was used as the mobile phase additive, the L-enantiomers of amino acids eluted before the corresponding D-enantiomers (**Figure 6A**). When the antipode was used as the ligand, the elution order was reversed (**Figure 6B**). Furthermore, no enantiomeric resolution of amino acids was observed with a racemic Cu(II)-proline complex (**Figure 6C**).

CDs or derivatized CDs were used for the enantioseparation of dansyl- or *t*-butyloxycarbonyl-amino acids as the chiral mobile phase additive. One macrocyclic antibiotic, LY33328, was used for the enantioseparation of nine dansyl amino acids.

### Introduction

Biotechnology, i.e., the development and application of expertise from the disciplines of biology, chemistry, and engineering, represents a rapidly growing modern industry, which is increasingly being considered an important driving factor in many of today's economies. The spectrum of biotechnological products covers a wide range from simple substances such as ethanol and citric acid through antibiotics and vaccines to the most advanced 'biopharmaceuticals'

such as recombinant proteins, antibodies, or DNA-based therapeutics. Concomitantly a wide range of production organisms and conditions are used by the industry, while the application spectrum of 'biotechnology' covers areas as diverse as agriculture, food science, general industry, and, perhaps most importantly, medicine.

However, there are certain common motifs in analytical biotechnology, which is mainly focused on process monitoring and control on the one side and quality control (identity, purity, stability) of the final product on the other. Monitoring the downstream process, i.e., product isolation and purification, then combines aspects of both areas. Analytical biotechnology has to operate within rather strict boundaries. In particular, the most precious

bioproducts (recombinant), proteins and DNA molecules, are not susceptible to analysis by methods such as gas chromatography and other standard high-resolution methods of analytical chemistry. In this context, liquid chromatography (LC) – together with the various electrophoretic methods – has been and will continue to be one of the major analytical techniques utilized for such work.

## LC

The most significant advantages of LC as an analytical technique in general are the diversity of parameters that can be used to achieve separation. For applications in analytical biotechnology, the most important of these parameters are size (gel permeation chromatography (GPC), size exclusion chromatography), charge (cation/anion exchange chromatography (IEC)), hydrophobicity/polarity (reversed-phase chromatography (RPC), hydrophobic interaction chromatography (HIC), normal-phase chromatography), and finally certain 'biospecific' interactions (affinity chromatography). By employing several of these techniques in series (multidimensional chromatography, e.g. IEC–HIC), highly orthogonal separation schemes can be drawn up that allow resolving even the most complex sample mixtures, e.g. for applications such as in 'proteomics'. An alternative to such 2D LC techniques is coupling a high-resolution LC technique such as RPC with a second analytical technique such as matrix-assisted laser desorption/ionization or electrospray ionization mass spectrometry, i.e., creating a so-called hyphenated technique. Especially when micro- or nano-LC techniques are used, hyphenated techniques have advantages in terms of sample size, speed, detection limit, and solvent consumption. The most recent developments, true microanalytical LC-systems, that work with capillary columns or perform the entire analysis on a microfluidic chip (total analytical system). In such systems the content of a single cell becomes in principle accessible to a detailed analysis.

### Separation Mechanisms

The various LC techniques available today to the analytical chemist are discussed in detail in other chapters and sections of this encyclopedia. Below therefore only the methods and features relevant to analytical biotechnology are briefly discussed. As the typical separation problems of analytical biotechnology are similar to those encountered in other areas of (bio)analytical chemistry, commercially available standard stationary phases and prepacked columns are used normally. The stationary phases are

normally porous or pellicular (solid), spherical particles with a diameter of 2 or 10  $\mu\text{m}$  and a very narrow particle size distribution (monosized beads) to ensure a high separation efficiency and minimum column back pressure simultaneously. Even complex separations can be carried out within minutes using such columns. In addition, so-called monolithic materials (UNO<sup>TM</sup>, BioRad USA, CIM<sup>TM</sup>-disks, BIA d.d.o, Slovenia) are being used increasingly, where the entire column consists of a single porous polymer block. Due to the improved mass transfer properties, such columns can be operated at extremely high flow rates without losing their efficiency.

**RPC** Reversed-phase high-performance liquid chromatography (RP-HPLC) is perhaps the most important LC method in analytical biotechnology. The stationary phase is usually a silica composite bearing hydrophobic hydrocarbon groups ( $\text{C}_2$ ,  $\text{C}_4$ ,  $\text{C}_8$ , or most often  $\text{C}_{18}$ ). Normally hydro-organic mobile phases (acetonitrile/water, methanol/water) are used, although variants using nonaqueous mobile phases have been reported. Elution is achieved by decreasing the polarity, i.e., increasing the organic content of the mobile phase. In the case of charged analytes, ion-pairing reagents such as trifluoroacetic acid (TFA) are added in small amounts to the mobile phase in order to reduce the nonspecific interaction between the analytes' charges with residual accessible silanol groups on the silica surface.

Due to their hydrophilicity, many biomolecules elute early in the gradient. While  $\text{C}_{18}$ -phases are still used in the majority of analytical applications, less hydrophobic phases bearing shorter hydrocarbon groups are gradually becoming available. Another consequence of the low hydrophobicity of typical biomolecules is the need for compatibility of the stationary phase with mobile phases of low organic solvent content. While most of the earlier  $\text{C}_{18}$ -phases, for example, could not be used with a mobile phase consisting of 100% water (irreversible collapse of the  $\text{C}_{18}$ -brush structure), today several column types are available that can be used with gradients ranging from 0 to 100% of an organic modifier in the mobile phase.

In analytical biotechnology, RP-HPLC is used for process monitoring, especially of media compounds such as certain amino acids but also for analysis of products such as antibiotics, enzymes, and other proteins. In addition, RP-HPLC constitutes the most important method for establishing the identity of many biotech products. In the case of recombinant proteins this may include the retention time of the product itself, the analysis of the amino acid composition, the analysis of the peptide map, as well

those of N-terminal variants, glycovariants, disulfide isomers, and proteolytic clips. Due to the volatility of its typical mobile phases, RP-HPLC has also become the method of choice for LC–mass spectrometry (MS) coupling.

**Ion-exchange chromatography** Ion exchangers can be divided into cation exchangers and anion exchangers, with a further division into strong and weak ones according to the functional groups. The choice between a cation and anion exchanger will depend upon the net charge of the analyte under the conditions used – anion exchange for negatively charged analytes and cation exchange for positively charged ones. Whether to use a strong or weak exchanger is a more difficult decision. The charge density of a strong ion exchanger is essentially independent of pH, but for a weak ion exchanger it is dependent upon the  $pK_a$  of the stationary phase. Ion exchange chromatography is carried out normally with an aqueous mobile phase (buffer) and tends to preserve biological activity to a high extent. Elution in IEC is accomplished by changing the pH or – most commonly – by increasing the ionic strength of the mobile phase.

In analytical biotechnology IEC is used for process monitoring (amino acids, sugars, certain media compounds and products) and for quality control purposes, for example, for determination of glycosylation variants or detection of deamidated product molecules (proteins). In addition, IEC type stationary phases are also used in many sample preparation schemes for rapid enrichment of the target molecule-containing fraction prior to further analysis.

While being a most powerful and widely used preparative separation technique, analytical IEC has the disadvantage of being difficult to couple to MS due to the need for a high salt elution buffer. For the same reason, miniaturization is difficult since high salt buffers are intrinsically unsuited for electrochromatographic applications, i.e., chromatographic separation, where the electro-osmotic flow is used to drive the mobile phase. Pressure-driven  $\mu$ -LC is possible in the IEC mode but is more difficult to perform.

**Gel filtration (size exclusion)** Gel filtration chromatography (also called size exclusion chromatography) employs porous beads with a defined pore size distribution as the stationary phase. Small molecules can enter the entire intraparticle pore space and hence elute last, whereas large molecules are excluded from all pores and hence elute first. Molecules of intermediate size are found that can enter a certain

portion of the intraparticle pores. For these molecules the column residence time is a direct function of their size and they can hence be separated according to this parameter. Retentive (or repulsive) interactions between the analytes and the stationary phases have to be avoided, and the chromatographic conditions (mobile phase composition, stationary phase material) have to be chosen accordingly. In analytical biotechnology, GPC is used mainly for quality control, e.g., to differentiate between dimers/product aggregates and the actual product during purity and stability testing.

**Affinity chromatography** In affinity chromatography the high specificity associated with the formation of a complex by two biological molecules is exploited. Ligands with specific binding sites, e.g., the antibody–antigen system, or group-specific molecules, e.g., lectins for the isolation of glycoproteins or Protein A for certain antibodies, can be used. Increasingly, affinity ligands are coming out of specific screening programs, based on, for example, combinatorial chemistry or biological systems such as phage display. The affinity ligand is linked covalently to an inert matrix. A spacer arm may be required, particularly for small molecules for decreasing matrix effects or steric hindrance to the interaction with the target molecules. Due to its high selectivity, affinity chromatography is a very important preparative technique in the biotechnological downstream process. In analytical biotechnology it is used in some cases to verify biological activity but mostly as a first capturing step for enriching a highly diluted product from the production stream prior to analysis using other techniques or for specific production rate monitoring during fermentation. The fact that often product variants (dimers, fragments, deamidated molecules, glycovariants) bind equally well to the affinity column may present a problem. Recently the coupling of affinity chromatography to MS has become more feasible, with in-line dialysis modules becoming available.

## Amino Acids

Determination of the amount and distribution of amino acids is required for a variety of bioanalytical questions. In bioprocess monitoring, the amount of certain free amino acids has to be monitored in order to avoid media depletion. In the case of a protein or a protein hydrolysate, analysis or verification of the amino acid composition may be a first step toward identification or characterization. The early work on amino acid analysis has been dominated by Stein and Moore, who in 1972 were awarded the Nobel prize

in chemistry for their work. The first dedicated amino acid analyzer was introduced by D.H. Spackman in 1950. Even today, the analysis of free amino acids is still done very much as proposed by these researchers, although considerable progress has been made in terms of the detection limit and the required sample volume. Analysis of free amino acids has to face two major difficulties. First, amino acids are small molecules that cover a wide range of polarity; they are therefore inherently difficult to handle for most LC techniques except IEC. Second, save for the aromatic amino acids, they possess almost no ultraviolet (UV) or fluorescence activity and can therefore only be detected using indirect methods, i.e., after labeling with a suitable dye. The introduction of a label prior to chromatography (precolumn labeling) will change the chromatographic behavior of the molecules and make them, for example, suitable for analysis using RP-HPLC. Compared with IEC, the separation will become faster and the resolution should improve in such cases.

Today, analysis of free amino acids is normally carried out using IEC together with postcolumn derivatization for detection or by RP-HPLC together

with precolumn derivatization (Figure 1). The detection limit of precolumn techniques tends to be one order of magnitude lower ( $<1$  pmol). At such levels, interference by impurities (microbial growth in column and/or buffer) may become a severe problem. The majority of the commercially available amino acid analyzers use IEC resins for the separation and ninhydrin as the postcolumn chromogenic reagent, although *ortho*-phthalaldehyde is gaining in popularity.

### Derivatization Reactions

Amino acids are derivatized in order to enable their detection by standard chromatographic detectors. Even today the perfect label has not been found. Such an ideal label should be easy to introduce in a defined manner (only one reaction product per amino acid) and should result in a stable and highly active (UV-absorbance, fluorescent activity) amino acid derivative, and it should be universal and react with all possible amino acids of interest.

**Dyes for postcolumn derivatization** Ninhydrin has been the standard reagent for detecting amino acids

**Figure 1** Separation of a physiological mixture of amino acids. (Reproduced with permission from Agnes H (ed.) (1985) *High-Performance Liquid Chromatography in Biochemistry*. Wiley-VCH, p. 156.)

for over 50 years. However, not all amino acids react equally well with ninhydrin, and the detection limit is  $\sim 50$  pmol ( $\sim 6$  ng) of amino acid derivative. The product of the reaction of *ortho*-phthaldialdehyde (OPA) with amino acids in the presence of thiol will fluoresce with excitation at 340 nm and emission at 450 nm. The reaction is fast (1–3 minutes), however, the OPA-derivatives are not stable. Secondary amino acids do not react and must first be converted into primary amino acids (oxidation with hypochlorite or chloramines-T (N-chloro-*p*-toluenesulfonamide)). The detection limit in the case of postcolumn derivatization with OPA is  $\sim 10$  pmol (1.2 ng). Fluorescein has also been proposed for postcolumn derivatization of free amino acids but is not widely used due to the many problems associated with its application.

**Dyes for precolumn derivatization** The Edman reagent (phenylisothiocyanate) can be used to form thiohydantoin derivatives of primary and secondary amino acids, which can be separated using RPC (detection UV 254 nm). The detection limit is  $\sim 1$  pmol ( $\sim 0.1$  ng). OPA is also used for the precolumn derivatization. Detection limits (fluorescence) down to the femtomole level are possible. Some other dyes are of limited importance in precolumn derivatization. 4-(Dimethylamino)azobenzene-4'-sulfonyl chloride reacts with amino acids to produce a derivative that is stable at room temperature and can be detected at the 3–5 pmol level using detection at 436 nm. 4-(Dimethylamino)azobenzene-4'-isothiocyanate in combination with RPC has a detection limit of  $\sim 5$  pmol with detection at 436 nm. Fluorenylmethoxycarbonyl chloride forms derivatives of all amino acids, including proline. UV detection is possible at 260 nm, and fluorescence detection (excitation 266 nm, emission 305 nm) is also possible, the detection limit being  $\sim 50$  fmol in that case. 5-(Dimethylamino)naphthalene-1-sulfonyl chloride also reacts with both primary and secondary amines. The derivatives can be detected using UV at 254 nm or using fluorescence (excitation 385 nm, emission 460 nm). The sensitivity is in the low picomole range. Due to some problems with the specificity and the completeness of the reaction, the dye is rarely used.

### Enantiomeric Separations

The need to resolve the D- and L-enantiomers of amino acids has grown in recent years as it has been recognized that they differ in biological and physicochemical properties. Amino acid enantiomers cannot be resolved in achiral systems; it is therefore necessary to have a second chiral center either in the chromatographic system or to create one by derivatization in the molecule to be separated (Figure 2).

Conversion of amino acids to produce a diastereoisomeric peptide by reaction with an *N*-carboxy-anhydride, e.g., L-Phe-*N*-carboxy-anhydride, has been used for determination of optical purity using RPC. Alternatively, for analysis of amino acid enantiomers without derivatization, two options are available: (1) chiral mobile phases such as the *N,N*-di-*n*-propyl-L-alanine-copper(II) complex can be used with reversed-phase columns, and (2) stationary phases with a covalently bound ligand capable of stereo recognition can be used. Such ligands include cyclodextrins, albumins, glycoproteins, and copper(II) complexes.

### Peptides, Proteins, 'Proteomics'

The analysis of peptides and proteins naturally has some analogies with that of their main building blocks, amino acids (Figure 3). The analysis of proteomes, i.e., the entire gene product spectrum expressed by a given organism (cell) at a given time, is a very recent development in protein analysis. Proteome analysis is largely dominated by 2D gel electrophoresis (orthogonal separation of the protein mixture according to isoelectric point and mass) as a literature survey will show that still well over 90% of the pertinent separations are carried out using this method. However, the application of orthogonal LC–LC and LC–MS techniques for this purpose is gaining ground.

For analysis of proteins and (synthetic) peptides, on the other hand, LC techniques are the method of choice (Figure 4). The problems encountered in analysis of free amino acids, namely the lack of an intrinsic detection method and the wide polarity range, are much less significant in the case of proteins/peptides. Since most of these molecules contain at least one aromatic amino acid and several peptide bonds, their UV detection at 280 nm and 214 nm, respectively, is straightforward. Since most peptides/proteins are made for a mixture of polar and non-polar amino acid residues, their separation using RP-HPLC in a gradient of increasing organic solvent is the most commonly used approach. The resolution of RP-HPLC is high enough to show clear differences between a protein and its variants (reduced, deamidated form, etc.) and also between the correct product of a peptide synthesis and peptides where one or several addition steps have failed. A second important method for protein characterization and identification is the peptide map. For this purpose the protein is digested by a protease such as trypsin (tryptic map) or chymotrypsin, and the resulting peptide mix is analyzed using RP-HPLC. Even single

**Figure 2** Analysis of eight amino acid racemates. Chromatography conditions: column MCI GEL CRS10W, eluent  $0.5 \text{ mmol l}^{-1}$  copper (II) sulfate, flow rate  $1.0 \text{ ml min}^{-1}$ , detection  $254 \text{ nm}$ , peaks 1 D-Ala, 2 L-Ala, 3 D-Pro, 4 D-Val, 5 L-Pro, 6 L-Val, 7 D-Leu, 8 D-Nle, 9 D-Tyr, 10 L-Leu, 11 D-Eth, 12 L-Tyr, 13 L-Nle, 14 D-Phe, 15 L-Eth, 16 L-Phe. (Reproduced with permission from Weston A and Brown Ph (1997) *HPLC and CE – Principles and Practice*. Academic Press, p. 61; © Elsevier.)

amino acid deviations can normally be detected as differences in the peak pattern given by the protein product and the variants. Peptide mapping is in addition very important for an indirect evaluation of the glycosylation pattern as the glycoform of a given peptide will show significant differences in the retention behavior compared with the nonglycosylated form. Finally, in combination with MS, the identity of the separated peptides can be determined and compared with the theoretical one in the case of proteins with known primary structure.

## Carbohydrates

Carbohydrate analysis has been slow to develop in comparison with that of other biologically important molecules. However, the more recent developments in biotechnology and renewable resources of raw materials have promoted interest in this diverse class

of compounds. Indeed, the term ‘carbohydrate’ encompasses a wide range of compounds from the simple building blocks (monosaccharides) to carbohydrate polymers, oligosaccharides, and polysaccharides and to various carbohydrate-containing species including glycoproteins, proteoglycans, nucleic acids, glycolipids, and antibiotics.

### Monosaccharides

There is a great variety in structure as well as chemical and physical properties of monosaccharides. There is no single method that is applicable to the qualitative and quantitative analysis of all monosaccharides; instead, the method must be chosen according to the chemical and physical characteristics of the solutes of interest. Borate complexes of monosaccharides can be separated using strong (quaternary amine, Q-type) anion-exchange columns. Alternatively, if the monosaccharide is acidic

or negatively charged at high pH, anion exchangers can be used directly. Cation-exchange chromatography is normally used for analysis of amino sugars and – using calcium as counterion – alditols and monosaccharides.

### Oligosaccharides

Oligosaccharides are traditionally defined as polymers of monosaccharides containing from two to ten

residues, although this range is often extended to 25 as naturally occurring polysaccharides rarely contain less than 25 repeat units. Anion-exchange resins with acetate, hydroxyl, or chloride counterions are usually used for oligosaccharide analysis. For a homologous series, the elution increases with increasing chain length. In an attempt to overcome the problems of interconversion of the terminal reducing residues of oligosaccharides, cation-exchange resins, in particular sulfonated poly(styrene–divinyl–benzene) materials, have been used for oligosaccharide separations, with water as the mobile phase. The effect of the counterion, e.g., lithium, barium, potassium, silver, or lead, is considerable as the separation mechanism is not purely cation exchange but also encompasses ligand exchange.

Gel filtration chromatography is another very useful technique for analysis of oligosaccharides. By a judicious choice of the stationary phase, a resolution of up to DP 15 can be achieved. The use of RPC for oligosaccharide analysis, on the other hand, has in general been limited to smaller oligomers owing to problems of solubility in the typical hydro-organic mobile phases. Normal-phase chromatography using stationary phases with amino or cyano functionalities has been used extensively for oligosaccharide analysis, again with aqueous acetonitrile mobile phases. However, unlike in RPC, elution takes place in a gradient of increasing water content of the mobile phase. Higher oligomers or polysaccharide material may be bound irreversibly to the column or have excessively long elution times.

**Figure 3** Determination of protein purity. Chromatographic conditions: column Hy-Tach micropellicular C-18 silica, eluent A 0.1% TFA in water, eluent B 95% acetonitrile in water containing 0.1% TFA, flow rate  $2.0 \text{ ml min}^{-1}$ , sample A  $40 \mu\text{g}$  carbonic anhydrase (gradient 15 to 55% B in 3 min), B  $40 \mu\text{g}$  L-asparaginase (gradient 30 to 40% B in 4 min), C  $40 \mu\text{g}$  myoglobin (gradient 23 to 45% B in 6 min). **Figure 5** Gel filtration chromatography of starch-derived oligosaccharides on a Bio-Gel P2 column. Peak numbers refer to the degree of polymerization.

### Polysaccharides

The number of liquid chromatographic methods available for analysis of polysaccharides is limited compared with those for monomers or oligomers. Polysaccharides comprise a diverse group of complex macromolecules that may range in molecular mass from several thousand to several million Daltons and may be composed of neutral, acidic, or basic monomers or mixtures thereof arranged in a variety of structures. As polysaccharides are polydisperse macromolecules, gel filtration is often the first liquid chromatographic method to be used for their characterization. As the separation mechanism is one based on solute size, columns can be calibrated with polysaccharides of known molecular masses, and estimates for unknowns can be made. IEC is used to assess the homogeneity of a polysaccharide, often in combination with gel filtration chromatography, to separate molecules of similar size on the basis of differences in their charges (Figure 5).

### Carbohydrate-Containing Macromolecules, Glycoproteins

The methods previously discussed for mono-, oligo-, and polysaccharides are also applicable to analysis of carbohydrate-containing macromolecules. For example, proteoglycans, which consist of a central core protein to which a number of glycosaminoglycan chains are attached, which carry a significant negative charge due to a high concentration of carboxyl and sulfate ester groups, can be separated using anion-exchange chromatography (Figure 6).

Of increasing importance in medical biotechnology is analysis of the glycosylation pattern, i.e., the composition and structure of the oligosaccharide chains of glycoproteins. While the amino acid sequence is encoded by the genetic code and can hence be transferred by genetic engineering from one

**Figure 6** HPAEC-PAD mapping of N- and O-glycans of glycoproteins after release by hydrazinolysis. (Reproduced with permission from Animal cell technology: products from cells, cells as products in *Proceedings of the 16th ESACT Meeting, April 25–29, Lugano, Switzerland*; © Kluwer Academic Publishers.)

species to the next, glycosylation is a post-translational event and hence shows pronounced differences from species to species and even between the different cell types of a given organism. At the same time glycosylation does have significant consequences for the biological activity as well as for the pharmacokinetics and -dynamics. A typical procedure in analysis of glycosylation patterns is comparison of the peptide map of the native glycoprotein and of that of the residual polypeptide structure after enzymatic release of the sugar residues together with a direct analysis of the released glycans using high-performance anion-exchange chromatography (HPAEC) with pulsed amperometric detection (PAD).

### Detection Methods

In general carbohydrates do not have a UV chromophore and do not fluoresce. Monosaccharides do absorb in the far UV, with the absorbance maxima at  $\sim 188$  nm. Detection is normally performed at wavelengths between 192 and 200 nm, where there is less residual noise in the detector signal, if the absorbance of the solvent permits this. The UV

**Figure 7** Ion exclusion isocratic separation of organic acids. Peaks: 1 chloride, 2 oxalate, 3 pyruvate, 4 tartrate, 5 malonate, 6 lactate, 7 malate, 8 acetate, 9 isocitrate, 10 citrate, 11  $\beta$ -hydroxy-*n*-butyrate, 12 succinate, 13 propionate. (Reproduced with permission from Dionex Product Selection Guide 1991.)

response is dependent upon the carbonyl group and will differ for the individual monosaccharides, fructose and glucose being the two extremes, with the response of fructose being six times that of glucose. Differential refractive index detection has often been used in the past; however, the method is not particularly sensitive and is only suitable for isocratic separations. Increasingly, PAD is being used as the universal method in the LC of mono- and oligosaccharides (Figure 7). The carbohydrate is oxidized at a gold electrode at a pH greater than 11, with the electrode surface being reduced back to gold using a negative potential sequence.

In addition, carbohydrates can be derivatized to produce UV or fluorescent species to improve detection. As with the amino acids, both precolumn and postcolumn derivatization are used. Precolumn derivatization influences the chromatographic behavior of the compounds. For UV detection, phenylisocyanate derivatization can be used together with RP-HPLC or benzoyl chloride and 4-bromobenzoyl chloride derivatization together with normal-phase chromatography. When fluorescence detection is preferred, dansyl hydrazine and aminopyridine derivatives can be analyzed using RPC.

Postcolumn derivatization is normally preferred for carbohydrate analysis as it is applicable to mono-, oligo-, and polysaccharides. It also improves the detection limit, and of course analysis selectivity, but without altering the intrinsic separation characteristics of the carbohydrates by introducing a group or groups that may dominate the separation process. The most common derivatization reactions are

automated versions of the spectrophotometric assays traditionally used for identification and quantification of carbohydrates. Methods of detection for total carbohydrate include the following: L-cysteine-sulfuric acid- and phenol-sulfuric acid-based assays for neutral carbohydrates, the carbazole assay or Warren assay for acid carbohydrates, the Elson Morgan assay for basic carbohydrates, and the 3,5-dinitrosalicylic acid assay for reducing groups.

## Organic Acids

Short-chain mono-, di-, and polycarboxylic acids are of significance to scientists studying amino acid degradation, metabolites of carbohydrate oxidation, and lipid breakdown. They can be indicators of human metabolic disorders and of importance in the biotechnology of food. LC is now the preferred method of analysis for these analytes irrespective of the sample origin – biological fluid, fermentation broth, or food.

IEC, or perhaps more correctly ion-exclusion chromatography using sulfonated polymeric resins, has become the method of choice for separating organic acids. The stationary phase can withstand extremes of pH, and the separation of the organic acids is normally according to  $pK_a$  values, but partition effects can also occur. Dilute acids are used as the mobile phase. Normally only isocratic mobile phases are required, with the addition of a small quantity of an organic modifier (usually acetonitrile) for analysis of nonpolar acids. In the case of weak organic acids, ion pairing agents can be used and the analysis can then also be achieved using RP-HPLC. However, this separation system is limited to certain organic acids, and the reproducibility can be poor. Detection can be achieved at nanogram or picogram levels, using electrochemical and conductivity detectors.

## Monitoring Fermentations and Fermentation Products

LC continues to be an important tool in fermentation monitoring. Using modern technology, the methods used are sufficiently fast and robust even for fermentation control, for example, to supervise nutrient addition and hence to maintain an optimum environment for the production organisms. Carbohydrates, amino acids, and the content of organic acids, all critical to either the production or the inhibition of production, can all be monitored as described above.

In the production of wine, monitoring the pyruvic acid content during malo-lactic fermentation gives an

indication of the health of the bacteria, a pyruvate being an indirect measure of NADH, the reducing co-factor that stimulates bacterial growth. Malates and tartrates are also simultaneously monitored, being indicators of the maturity of the fermentation process. Lactose fermentation can yield lactic, acetic, pyruvic, formic, propionic, and butyric acids, which are indicators of the flavor and stability of dairy products. All these acids can be determined in one LC-analysis run.

In the food industry LC is frequently used to determine the quality of the finished product. For example, it has been shown that the flavor quality of grape juice is directly linked to the amount and spectrum of organic acids present. Likewise, in the production of sour cream by fermentation, the quality of the finished product quality is related directly to the organic acid profile. Last, but not least and as pointed out above, LC techniques are also crucial in determining the quality of recombinant protein products.

## Introduction

The diagnosis and monitoring of many disease states relies on the detection and quantitation of a particular compound(s) or metabolite(s) in body fluids, usually blood or urine. A wide variety of techniques are used in the clinical chemistry laboratory with spectrophotometric and immunoassay methods on automated analyzers measuring single compounds

predominating. In some instances a family of compounds may need to be measured and it is in these situations where the chromatographic techniques are important to avoid the necessity for a separate assay for each component of interest in the mixture.

Initially chromatography was carried out using paper or slab gels. The use of columns to contain the stationary phase came more recently with the advent of high-performance liquid chromatography (HPLC). Typical applications of HPLC in clinical chemistry include:

1. Biogenic amines
  - (a) Catecholamines and metabolites
  - (b) Serotonin and metabolites

2. Drugs
  - (a) Anticonvulsants
  - (b) Miscellaneous
3. Amino acids
4. Porphyrins
5. Vitamins
6. Carbohydrates
7. Glycohemoglobin

These applications will be described in greater detail in this article. Many other specific applications have been developed for particular projects, including separations of nucleosides and collagen breakdown products, but these have not commonly transferred from the research environment to the routine repertoire of tests.

Whilst 10–15 years ago the use of HPLC in the clinical laboratory was only found in the larger laboratory or where it was the particular interest of an individual, improvements in the equipment have permitted the extension of the technique to many more laboratories. In particular, HPLC with electrochemical detection is now the method of choice for the measurement of catecholamines and their metabolites and this has resulted in a much wider user base. HPLC does not readily lend itself to the analysis of large numbers of samples nor does it typically produce rapid results, although recent developments in the analysis of glycohemoglobins are changing this. The type of application most suited to a HPLC solution, therefore, has a small number of samples requiring a complex analysis without the need for a very rapid throughput. Reversed-phase chromatography is particularly suited to the separation of uncharged species. One of the problems encountered with the use of HPLC with clinical samples is that many of the compounds of interest are charged at physiological pH. This may be overcome by the use of ion-pairing agents in the extraction buffers and/or mobile phase.

## Sample Preparation for Biological Samples

The majority of applications of HPLC in clinical laboratories are based on the use of blood, plasma/serum, or urine samples, although feces and tissue samples are also used. The high protein content of blood samples ( $\sim 70 \text{ g l}^{-1}$  in plasma or serum) necessitates some form of sample pretreatment prior to injection onto the column to reduce background interference and to avoid column clogging. The specific preparation steps found most appropriate for the applications listed above will be described in the

relevant sections, but typically deproteinization and/or extraction of the compounds of interest is carried out. Both liquid–liquid and solid-phase extractions are used in the clinical laboratory. When urine is used, the presence of colored/fluorescent pigments in the sample may cause difficulties when ultraviolet (UV) or fluorescence detection is used and some form of extraction is usually required to eliminate this interference.

## Biogenic Amines

**Catecholamines and their metabolites** The catecholamines, adrenaline, noradrenaline, and dopamine are essential components of the central nervous system acting as neurotransmitters both within the brain and at peripheral nerves. All are synthesized in the adrenal medulla from phenylalanine or tyrosine and are metabolized by a mixture of enzymatic side chain oxidation and methylation of the hydroxy groups on the ring. If the metabolism is complete, adrenaline and noradrenaline are degraded to 4-hydroxy-3-methoxy mandelic acid (HMMA, commonly called vanillylmandelic acid – VMA), while dopamine is broken down to homovanillic acid (HVA). Urinary excretion of these metabolites and their conjugates is the major route of elimination of catecholamines from the body, although small amounts are excreted unchanged as the free catecholamines.

Measurement of the catecholamines and a variety of the intermediate metabolites in blood or tissue is common in psychiatric and neurochemical research. In clinical chemistry the major interest in catecholamine metabolism surrounds the detection and location of the tumors of neural crest origin – pheochromocytoma and neuroblastoma. These tumors are fortunately rare but their identification is important because if treated promptly they may be curable. Pheochromocytoma is associated with secretion of adrenaline and/or noradrenaline into the bloodstream and can either be detected by the increase in the parent compounds or by increased VMA excretion. The most common presentation by the patient is hypertension unresponsive to conventional therapy. Neuroblastoma is the commonest malignant soft tissue tumor of childhood, arising from ectodermal neuroblasts. These tumors secrete abnormally high concentrations of dopamine which is largely metabolized to HVA.

Various strategies for the identification of these tumors have been employed. Prior to the advent of reliable HPLC methods, thin-layer chromatography (TLC), or colorimetric assays for VMA and HVA in urine were the most frequently used

measurements, although fluorimetric assays for catecholamines were also utilized by some laboratories. Plasma catecholamines, urine catecholamines, and the metabolites can be measured by HPLC. Two detection techniques, fluorimetric (with and without derivatization) and electrochemical (both amperometric and coulometric), provide the required sensitivity and specificity for quantitation of the catecholamines.

**Plasma catecholamines** The catecholamines are present in human blood plasma in the low nanomolar range, hence some preconcentration, extraction, and sample cleanup of endogenous electrophores is required prior to analysis. The catecholamines from 1 to 3 ml of plasma are adsorbed onto alumina and then eluted into 100  $\mu$ l of acid to give a 10–30-fold increase in concentration. Preparation of trihydroxyindole derivatives provides sufficient sensitivity for fluorescent detection. Reversed-phase (C18) columns with addition of an anionic ion-pair reagent or specific ion-exchange columns are suitable, producing separation of all three catecholamines within 15–20 min with isocratic elution. Electrochemical detection provides acceptable specificity with an oxidation potential of +0.75 V when using amperometry.

**Urine catecholamines** The catecholamines are present in urine in low micromolar concentrations, 1000-fold higher than in plasma, their measurement therefore being considerably easier than in plasma. A wide variety of extraction methods have been published including both liquid–liquid and solid-phase extraction. Many of the liquid–liquid extraction methods are based on the formation of complexes between the catecholamines and diphenylborate in an organic solvent with subsequent back-extraction into acid. Ion pairing with tetrabutylammonium bromide or a similar ion-pairing reagent produces good resolution of the catecholamines when a C18 reversed-phase column is used (Figure 1). Dihydroxybenzylamine is suitable as an internal standard as it behaves in a similar manner to the catecholamines in most extraction procedures and can be resolved from the majority of interfering substances found in urine.

**Urinary metabolites VMA and HVA** The metabolites are present in urine at much higher concentrations than the catecholamines – 10–50  $\mu$ mol l<sup>-1</sup>. They are readily extracted from acidified urine into ethyl acetate which can then be evaporated off and the residue dissolved in the mobile phase of choice. VMA is only weakly retained on C18 columns and

**Figure 1** Chromatographic profile of a urinary extract of catecholamines using a C18 reversed-phase column. The catecholamines are extracted into a hexane:octanol mixture by complex formation with diphenylborate in alkaline solution and ion-pair formation with tetrabutylammonium bromide. The catecholamines are back-extracted into hydrochloric acid. Mobile phase: phosphate buffer pH 5.5/methanol (87.5:12.5). Flow rate 1.2 ml min<sup>-1</sup>. Detection: electrochemical oxidation at +0.65 V vs Ag/AgCl with glassy carbon electrode. Column: ODS Hypersil 5  $\mu$ m, 15 cm  $\times$  4.6 mm.

careful choice of conditions is required to resolve it from the solvent front and other early eluting compounds. Phosphate buffer (pH 3.0) modified by the addition of methanol (15–20%) resolves VMA adequately without producing unacceptably long retention times for HVA (Figure 2). Virtually all the methods described utilize electrochemical detection with an oxidation potential between +0.65 and +0.75 V.

**The indoleamines** The indole of greatest significance in human metabolism is serotonin (5-hydroxytryptamine (5-HT)) which is synthesized from tryptophan and metabolized by the monoamine oxidase system to 5-hydroxyindole acetic acid (5-HIAA). Serotonin is believed to play a significant role in maintenance of mood and many antidepressant drugs act via the serotonergic receptor system.

**Figure 2** Chromatographic profile of a urinary extract of catecholamine and indoleamine metabolites using a C18 reversed-phase column. VMA, HVA, and 5-HIAA are extracted with ethyl acetate, evaporated to dryness, and redissolved in mobile phase. Mobile phase: phosphate buffer pH 3.0/methanol (82:18). Flow rate  $1.0 \text{ mL min}^{-1}$ . Detection: electrochemical oxidation at  $+0.75 \text{ V}$  vs Ag/AgCl with glassy carbon electrode. Column: ODS Hypersil  $5 \mu\text{m}$ ,  $15 \text{ cm} \times 4.6 \text{ mm}$ . The internal standard (IS) is 5-hydroxy-2-indolecarboxylic acid.

Carcinoid tumors arising from the argentaffin cells of the gastrointestinal (GI) tract secrete excessive amounts of serotonin, the local action of which in the gut provokes diarrhoea. Measurement of serotonin or 5-HIAA is useful in the detection of carcinoid tumors and in monitoring therapy.

**Serotonin** In blood serotonin is predominantly located in the platelets, with levels in plasma being  $\sim 100$ -fold lower. Most analysts interested in serotonin measurements have concentrated on determining serotonin in whole blood or platelet rich plasma. The presence of monoamine oxidase enzymes in blood necessitates the use of an enzyme inhibitor, e.g., pargyline to prevent the conversion of serotonin to 5-HIAA prior to analysis. Similar chromatographic conditions to those used for catecholamines can be used, e.g., C18 reversed-phase columns and electrochemical detection at an oxidation potential of  $+0.75 \text{ V}$  or fluorescence detection. Sample

preparation is complicated by the use of whole blood as the sample matrix, but both protein precipitation methods and solid-phase extraction have been used successfully. Measurement of serotonin in platelet poor plasma is much more difficult due to the much lower concentrations and protein precipitation or direct injection methods have been described.

**5-HIAA** The Urinary concentration of 5-HIAA is of the same order as VMA and HVA, e.g.,  $10\text{--}50 \mu\text{mol l}^{-1}$ . Many of the methods developed for urine VMA and HVA can also be used for the assay of 5-HIAA (Figure 2). Relatively few methods have been reported for the determination of 5-HIAA in plasma as both the concentration and the difficulties are similar to those encountered for HVA and 3-methoxy-4-hydroxyphenylglycol (MHPG). Both fluorimetric and amperometric methods have been described.

## Drugs

Drug analysis is of interest to clinical chemists for two main purposes; the identification and quantitation of drugs used for recreational purposes and the monitoring of therapeutic drugs. The former is usually confined to the investigation of patients suspected of drug misuse or where there is a possibility of accidental or deliberate overdose. Toxicological analysis is a specialized area and will not be discussed further in this article. Therapeutic drug monitoring (TDM) has become a routine part of most clinical chemistry laboratory repertoires particularly for anticonvulsant, antiasthmatic, and antiarrhythmic drugs. A mixture of immunoassay and chromatographic methods can be found for these drugs with individual laboratory's preferences being defined by a number of factors including: cost, availability of equipment, staff resources, and required turnaround times. Assay of the antibiotics usually falls within the remit of microbiology rather than clinical chemistry departments with immunoassay techniques being used in most instances.

The general principles for selecting whether TDM is appropriate for a particular drug are based on the occurrence of interindividual variation in the rate and extent of drug absorption, distribution, metabolism, and excretion of the drug. The dosage required to maintain an effective serum concentration may vary considerably between individuals particularly for drugs with a narrow therapeutic index. Plasma or serum drug concentrations can therefore help in establishing initial dosage regimens and in making adjustments to optimize therapy.

**Anticonvulsants** Anticonvulsants were one of the first groups of drugs for which TDM was indicated. The common anticonvulsants encountered in clinical practice are: phenobarbitone, primidone (metabolized to phenobarbitone), phenytoin, carbamazepine, ethosuximide, and valproate. The majority of assays for these drugs are immunoassays these days as 24 h availability of measurements of these drugs has become the general expectation.

The major disadvantage of immunoassays is the need to carry out one assay for each drug or drug metabolite of interest. For example, carbamazepine has a metabolite carbamazepine-10-11-epoxide which may be biologically active and which may need to be measured on occasion. HPLC can be used to profile the first four to five of the listed drugs in a single analytical run (Figure 3). Numerous liquid-liquid or solid-phase extractions have been described for the anticonvulsants, the difficulty being to obtain acceptable recoveries from the differing compounds. Reversed-phase chromatography on C18 columns has been almost universally used with an isocratic methanol/buffer system. Detection is relatively easy with strong UV maxima between 200 and 250 nm.

There is a new generation of anticonvulsants for which the need for TDM is currently being determined including: lamotrigine, gabapentin, vigabatrin, topiramate, and leviteracetam. For gabapentin and vigabatrin the plasma concentration has little relationship with clinical efficacy, and TDM is only useful for assessing compliance. For the others there may be other indications for TDM. All can be measured by reversed-phase HPLC, usually with UV detection.

**Miscellaneous drugs** The number of drugs that can be measured in human samples runs into thousands. Most of these are only measured for specific projects or initial pharmacokinetic studies. The other types of drug routinely measured for TDM purposes include:

- antidepressants, e.g., amitriptyline, clozapine, etc.
- immunosuppressive drugs, e.g., cyclosporin A
- cardioactive drugs, e.g., amiodarone

The above-mentioned examples all have active or inactive metabolites which can be measured by HPLC, but not by typical immunoassay methods. Where the metabolites are active, their measurement can be beneficial in interpreting the results. For cyclosporin A up to 21 metabolites are known, but the biological activity of most of these is uncertain. HPLC is the reference method for the parent

**Figure 3** Chromatogram of a plasma extract showing separation of the anticonvulsants primidone, phenobarbitone, phenytoin, and carbamazepine by isocratic reversed-phase chromatography. Solid-phase extraction with a C18 column was used for sample preparation. Methanol (45%) in dilute acid is used as the mobile phase. Flow rate  $1.0 \text{ ml min}^{-1}$ . Detection: UV absorption at 225 nm. Column: ODS Hypersil  $5 \mu\text{m}$ ,  $15 \text{ cm} \times 4.6 \text{ mm}$ . Two internal standards are used; IS 1 is 4-methyl primidone and IS 2 is 5-ethyl-5-*p*-tolylbarbituric acid.

compound as most antibodies currently available have some cross-reactivity with the metabolites. Mass spectrometry (MS) has been used as a mode of detection in combination with gas chromatography for many years. The large fluid volumes in HPLC in comparison prevented the combination of HPLC and MS initially. The introduction of microbore HPLC and developments in the production of very fine liquid aerosols (electrospray) have resulted in

LC-MS becoming widely available. LC-MS or tandem MS (MS-MS) may replace HPLC alone as the standard methodology for the immunosuppressive drugs.

### Amino Acids

Amino acid analysis in clinical chemistry is of importance in the diagnosis and monitoring of the inherited disorders of amino acid metabolism and is also of value in many nutritional studies. Qualitative or semiquantitative identification of the most important amino acids may be achieved using TLC but quantitation is often necessary particularly for the monitoring of therapy in disorders such as phenylketonuria or maple syrup urine disease. The traditional amino acid analyzer (the first specialist HPLC system) is based on separation of the amino acids by cation-exchange chromatography with spectrophotometric detection following postcolumn derivatization with ninhydrin. Although this approach is still the commonest technique found in clinical chemistry laboratories, it has relatively poor sensitivity and long analysis time (up to 4 h) and HPLC methods are now beginning to appear that could replace it.

The presence of large amounts of protein can have a major effect on the determination of free amino acids in plasma and samples must be deproteinized prior to analysis. Protein precipitation with either acid or organic solvent may be used, although care should be taken when acids are used to avoid interference in the chromatography from the acid itself.

To achieve increased sensitivity and reduced analysis time it is necessary to produce derivatives of the amino acids which can be separated by reversed-phase HPLC and then detected using fluorescent, spectrophotometric, or electrochemical detection. Both precolumn and postcolumn derivatization methods have been described with a range of derivatizing agents including:

- dabsyl chloride,
- dansyl chloride,
- 9-fluorenylmethyl chloroformate (FMOC),
- *o*-phthalaldehyde (OPA), and
- phenylisothiocyanate (PITC).

The first four derivatizing agents listed above produce products suitable for fluorescent detection while PITC derivatives can be measured spectrophotometrically or electrochemically. Both dansyl and dabsyl chloride must be added in considerable excess to give reasonable sensitivity necessitating the removal of

the excess sulfonic acid by-products which cause interference if allowed to remain. A similar problem occurs with the use of FMOC as it forms fluorenylmethyl alcohol which must be removed prior to chromatography. Until recently OPA was the most commonly used derivatizing agent for HPLC amino acid analysis. In the presence of a thiol reagent such as mercaptoethanol, OPA, which is itself not fluorescent, reacts with primary amines to form highly fluorescent isoindoles well suited to reversed-phase separation. The OPA derivatives with aliphatic amines are unstable but the use of automated sample preparation systems has made this less of a disadvantage and stable derivatives with OPA and *N*-acetyl-cysteine have now been described. A much more significant disadvantage for clinical chemists is the nonreactivity of OPA with the imino acids proline and hydroxyproline and the low sensitivity to cysteine. Several approaches have been reported to overcome this problem including the postcolumn addition of hypochlorite and a dual derivatization method using both OPA and FMOC.

The Edman reagent, PITC, has for many years been used in protein sequencing and has more recently been adapted for amino acid analysis in body fluids. The phenylthiocarbamyl derivatives formed can be detected either by their UV absorption at 254 nm or by electrochemical detection at an oxidation potential of +1.1 V. Derivatives are formed with both primary and secondary amino acids although sensitivity to cysteine and homocysteine is lower than for the other amino acids. Use of gradient elution with a mobile phase containing acetate buffer and acetonitrile permits resolution of the majority of the physiological amino acids within 50 min (**Figure 4**), although the time required for reequilibration of the system results in a total cycle time of 70–80 min. Modification of the gradient profile can significantly reduce the overall run time if only a single amino acid or related group of amino acids are required. For example a total run time of 25 min can be achieved for the measurement of glycine and hydroxyproline. The derivatives are stable at 4°C for several days and for longer periods at –20°C. The derivatization process is relatively simple but cannot be readily automated. Very few compounds found in body fluids interfere, although some of the cephalosporin antibiotics produce peaks as does the anticonvulsant vigabatrin (a gamma-amino-butyric acid analog). Quantitation is reproducible with between batch CVs of 8–12% for most amino acids.

As for the immunosuppressive drugs, the advent of affordable and reliable tandem MS has meant that many laboratories providing a neonatal screening

**Figure 4** Chromatogram of PITC derivatized amino acid standards. Initially the mobile phase is a phosphate buffer, pH 6.2, containing 0.7% acetonitrile. A linear gradient is used to increase the acetonitrile concentration to 70%. The internal standard is norleucine. Flow rate  $1.0 \text{ ml min}^{-1}$ . Detection is at 254 nm. Column: ODS Hypersil  $5 \mu\text{m}$ ,  $25 \text{ cm} \times 4.6 \text{ mm}$ .

service for phenylketonuria are evaluating, changing from TLC/HPLC to LC-MS methods.

### Porphyryns

The porphyrin family of compounds are cyclic tetrapyrroles many of which are intermediates of the heme biosynthetic pathway. The majority of the compounds of interest to the clinical chemist are not in fact porphyrins (with the exception of protoporphyrin) but porphyrinogens in which all four methylene bridges are in the reduced form. The significance of the porphyrins in medicine relates to the class of inherited disorders – the porphyrias – where there is accumulation of the precursors due to an enzyme deficiency in the heme pathway. The clinical presentation of the porphyrias varies from a chronic photosensitivity to severe acute abdominal pain as in acute intermittent porphyria, which may be precipitated by exposure to certain drugs. Characterization of the type of porphyria depends upon the identification of particular patterns of porphyrins in blood, urine, and feces.

Early methods for porphyrin HPLC were based on the formation of methyl esters followed by normal

phase chromatographic separation. These had the disadvantage of not distinguishing between the types I and III porphyrin isomers and with the advent of reversed-phase systems for porphyrin separation are only used for unusual cases today. Porphyrins can be extracted and concentrated from urine by adsorption with acidified acetone. An acid/ether extraction will separate the porphyrins in feces from interfering chlorophyll or carotenoid pigments, whilst ethyl acetate-acetic acid is the preferred extraction method for red blood cell or plasma porphyrins. Once extracted the porphyrin free acids can be separated using a C18 reversed-phase column with an ammonium acetate-acetonitrile mobile phase. Varying the proportion of acetonitrile in the mobile phase from 13% to 30% permits the separation of particular groups of the porphyrins with the uroporphyrins eluting at the lower acetonitrile concentration and the coproporphyrins at the higher concentration. Gradient elution using a linear gradient of acetonitrile-ammonium acetate will resolve the 17 most important porphyrins including the types I and III isomers within 40 min. Detection of porphyrins can be achieved by measuring their UV absorption at

404 nm or by fluorescence emission at 580 nm after excitation at 395 nm.

## Vitamins

The technique of HPLC has had a marked impact on the assay of vitamins in body fluids. Whilst linked by function the vitamins are a diverse group of compounds, but virtually all have been measured in blood or urine by HPLC. All the fat soluble vitamins, A, D, E, and K, are measurable by HPLC as are most of the water-soluble B vitamins and vitamin C. In some cases, notably folate, B<sub>12</sub> and vitamin D immunoassay methods are routinely used to achieve sufficient sensitivity for clinical purposes and these vitamins have not been discussed further in this article.

**Vitamin A and the carotenoids** The majority of the dietary provitamin carotenoids, e.g., B-carotene, are oxidatively cleaved to vitamin A (retinol), although an appreciable fraction circulates intact in plasma. Retinol in plasma forms a complex with retinol-binding protein and it is this that is usually measured as an indication of vitamin A status in individuals. The complex can be disrupted by ethanol and retinol or B-carotene can then be extracted into hexane. Separation can be achieved with C18 reversed-phase columns with elution by methanol. Detection of retinol may be achieved either from its UV absorption at 325 nm or its native fluorescence, while B-carotene absorbs in the visible region.

## The B vitamins

**Thiamin (vitamin B<sub>1</sub>)** Thiamin in the body is chiefly found in the phosphorylated form thiamin pyrophosphate (TPP) which is a coenzyme. The majority (80%) of thiamin in the blood is found in the erythrocytes and assay of blood thiamin is a more reliable indicator of deficiency than assay of erythrocyte transketolase. The phosphorylated vitamers are enzymically converted to thiamin in samples using diastase following deproteinization. To reach the low picomolar concentrations the thiamin compounds are oxidized by ferricyanide to form thiochromes, which are highly fluorescent. The thiochromes are then separated by reversed-phase HPLC and detected by their emission at 425–450 nm.

**Riboflavin (vitamin B<sub>2</sub>)** Riboflavin exists primarily as the coenzyme forms flavin mononucleotide and flavin adenine dinucleotide. Not commonly measured, both can be measured by their natural fluorescence at 530 nm following reversed-phase

separation. Urine may be injected directly, while in other fluids deproteinization is necessary.

**Nicotinic acid and nicotinamide** These are sometimes known by the generic term niacin. Their importance is in combination with tryptophan, as the coenzyme forms nicotinamide adenine dinucleotide (NAD<sup>+</sup>) and nicotinamide adenine dinucleotide phosphate (NADP). HPLC is too insensitive to measure endogenous plasma levels, but the urinary metabolites *N*-methyl-2-pyridone-5-carboxylamide and *N'*-methylnicotinamide can be measured to assess niacin status. Preliminary cleanup of urine by anion-exchange resins is followed by reversed-phase HPLC with UV detection.

**Vitamin B<sub>6</sub>** Vitamin B<sub>6</sub> is the generic name for six naturally occurring vitamers which are derivatives of 2-methyl-3-hydroxy pyridone. All forms of vitamin B<sub>6</sub> have been detected in human plasma with the exception of pyridoxine phosphate. Both free and protein bound forms can be extracted with trichloroacetic acid or perchloric acid, the excess of which should be removed prior to chromatography. Cation-exchange chromatography with linear gradients of hydrochloric acid and phosphate buffers produces a profile of the vitamin B<sub>6</sub> compounds in 50 min.

**Vitamin C** Vitamin C activity resides in two naturally occurring compounds; ascorbic acid and its oxidation product, dehydroascorbic acid. In human tissues ascorbic acid predominates. Ascorbic acid is labile in most samples, oxidizing to dehydroascorbic acid and then degrading to 2,3-diketogluconic acid. Various reagents can be used to prevent this oxidation in plasma or whole blood samples. Extraction with 5% metaphosphoric or trichloroacetic acid is the usual initial preparation. Only ascorbic acid may be detected by UV spectrophotometry at 245–265 nm, the absorption maxima of dehydroascorbic acid being 210 nm. A similar problem exists with electrochemical detection where ascorbic acid oxidizes at +0.7 V with carbon electrodes. Fluorescent derivatives may be formed with 2-4-dinitrophenylhydrazine or *o*-phenyldiamine. These derivatives can be assayed by reversed-phase HPLC.

**Vitamin E** In man  $\alpha$ -tocopherol is the major form of vitamin E activity found in plasma and cells with  $\beta$ - and  $\gamma$ -tocopherol being minor components all of which are bound to lipoproteins. With a plasma concentration of 5–15 mg l<sup>-1</sup>,  $\alpha$ -tocopherol has the highest plasma concentration of any of the fat soluble vitamins. For the separation of the tocopherols, reversed-phase HPLC can be used. Though the molar

extinction coefficient of vitamin E in the UV region is relatively low, the plasma concentrations are sufficiently high to allow UV detection. Tocopherols exhibit native fluorescence and can also be detected electrochemically at an oxidation potential of  $+0.7\text{ V}$ .

**Vitamin K** HPLC has provided the first assay of the phyloquinones and menaquinones that constitute vitamin K in plasma. Phyloquinone circulates bound to lipoproteins from which it can be extracted with hexane after ethanol protein precipitation. Removal of co-eluted lipids can be achieved with normal-phase cartridge columns. Reversed-phase HPLC is almost universally used for vitamin K measurement. Either UV (270 nm) or electrochemical detection is suitable. Electrochemical detection uses the reductive mode ( $-1.3\text{ V}$ ) to convert the quinone moiety to hydroquinone; the main disadvantage being the need to remove oxygen from the mobile phase.

### Carbohydrates

Apart from the measurement of glucose, perhaps one of the most frequently undertaken tests in medicine, the need to quantitatively assay the many carbohydrates in the body has fortunately been uncommon. TLC methods have sufficed for the screening of samples for the inherited disorders of carbohydrate metabolism such as galactosemia or fructosuria. Recent developments of multiple sugar absorption tests to assess small bowel permeability have necessitated a reassessment of the available methods for separation and quantitation of specific carbohydrates in urine. Lactulose, rhamnose, xylose, and 3-*o*-methylglucose cross the wall of the gut via different mechanisms, and consumption of a solution containing these sugars combined with measurement of the percentage of each sugar excreted in urine over a 5 h period can assist in the differential diagnosis of GI tract disease.

The carbohydrates are a problematical group of compounds from the point of view of detection, having neither useable spectrophotometric or fluorescent properties. The method of choice for detection of carbohydrates in pure solution has been refractometry but interference from other compounds in body fluids and its relative insensitivity has limited its application in clinical chemistry. The development of pulsed amperometric detection at noble metal electrodes and improvements in anion-exchange columns has now made possible the separation and quantitation of most carbohydrates of interest in urine samples. As ion-exchange columns require a constant ionic concentration to achieve consistent separations, urines are first desalted with

Amberlite resin prior to injection into a dilute sodium hydroxide mobile phase. This provides the alkaline environment suitable for pulsed amperometry, although if reversed-phase chromatography provides better resolution of the carbohydrates under study, postcolumn addition of hydroxide can be carried out.

### Glycohemoglobin

There are relatively few applications of HPLC to protein separations in clinical chemistry, electrophoresis being the preferred technique. An exception to this is the separation of glycohemoglobins using weak cation-exchange chromatography. Separation of the glycosylated fraction HbA1c from the nonglycosylated HbA1a and HbA1b can be achieved using HPLC, and dedicated automated systems are available with analytical cycle times of 4–8 min; suitable for use in the clinic setting. A disadvantage of the ion-exchange chromatographic methods is their inability to separate the abnormal hemoglobins, HbS and HbC and their glycosylated equivalents, from the normal HbA and HbA1c peaks without significantly lengthening the run time. A similar automated column chromatography method is available based on the principle of affinity chromatography. The glucose residues on the hemoglobin bind to a boronate agarose affinity gel and are eluted subsequently with sorbitol. This method is not affected by the charge on the hemoglobin and can measure the glycated fractions of the variant hemoglobins. A reference method has been established which involves cleavage of hemoglobin into peptides by the endoproteinase Glu-C followed by separation and quantitation of the hexapeptides by HPLC–electrospray ionization mass spectrometry (ESI-MS) or HPLC–capillary electrophoresis (HPLC–CE).

### Introduction

Liquid chromatography (LC) has become a very useful tool in the area of food analysis. Its use and development have increased in parallel with consumers' concern about the composition and the safety of food. Moreover, the Nutrition Labeling and Education Act in the United States and the new regulations in the European Union countries (E.G. Regulation EC 258/97 or EN 29000 and subsequent issues) have had a major impact on food laboratories, consequently increasing their requirements in terms of faster, more powerful, and cleaner procedures to analyze foods. Analytical techniques such as LC must address a number of important problems and must provide fast and accurate information about processing and food quality while ensuring compliance with laws relating to food, trade, adulteration, contamination, food tampering, and chemical composition of foods. All these requirements have increased interest in LC. The reasons for its popularity are easy to find: wide range of applicability, allowing the separation of compounds ranging from ions to biopolymers, mild separation conditions (low temperature), which preclude the decomposition of thermally labile compounds such as vitamins, good sensitivity and resolution, and a wide range of separation mechanisms, which favor the separation of different types of compounds.

High-performance LC (HPLC) is the technique used most frequently in food analysis for measuring carbohydrates, vitamins, additives (sweeteners, antioxidants, colorants, preservatives, etc.), mycotoxins, amino acids, proteins, triglycerides in fats and oils, lipids, chiral compounds and pigments, among others (Table 1). Some of these applications will be discussed in this article.

One of the main problems that LC has to encounter is the complexity of the samples that have to be analyzed, with the selected analyte being usually present in very low levels. There are several ways of overcoming this problem in LC, e.g., increasing the specificity of the separation method and improving

### Introduction

Liquid chromatography (LC) has become a very useful tool in the area of food analysis. Its use and development have increased in parallel with consumers' concern about the composition and the safety of food. Moreover, the Nutrition Labeling and Education Act in the United States and the new regulations in the European Union countries (E.G. Regulation EC 258/97 or EN 29000 and subsequent issues) have had a major impact on food laboratories, consequently increasing their requirements in terms of faster, more powerful, and cleaner procedures to analyze foods. Analytical techniques such as LC must address a number of important problems and must provide fast and accurate information about processing and food quality while ensuring compliance with laws relating to food, trade, adulteration, contamination, food tampering, and chemical composition of foods. All these requirements have increased interest in LC. The reasons for its popularity are easy to find: wide range of applicability, allowing the separation of compounds ranging from ions to biopolymers, mild separation conditions (low temperature), which preclude the decomposition of thermally labile compounds such as vitamins, good sensitivity and resolution, and a wide range of separation mechanisms, which favor the separation of different types of compounds.

High-performance LC (HPLC) is the technique used most frequently in food analysis for measuring carbohydrates, vitamins, additives (sweeteners, antioxidants, colorants, preservatives, etc.), mycotoxins, amino acids, proteins, tryglicerides in fats and oils, lipids, chiral compounds and pigments, among others (Table 1). Some of these applications will be discussed in this article.

One of the main problems that LC has to encounter is the complexity of the samples that have to be analyzed, with the selected analyte being usually present in very low levels. There are several ways of overcoming this problem in LC, e.g., increasing the specificity of the separation method and improving

the selectivity of both the sample preparation prior to LC analysis and the LC analysis itself.

In terms of the specificity of the separation method, it is possible to select the most appropriate separation mechanism by choosing from a wide range of stationary phases, detectors, and mobile phases. Thus, not only can elution power be altered by changes in mobile-phase composition but selectivity can also be changed using mobile-phase additives such as chiral compounds or ion pair reagents. A new and very specific type of LC is affinity chromatography, which provides high selectivity and specificity for separating compounds able to form a complex with a ligand (immobilized on the chromatographic support), thus allowing specific determination of the major compounds, such as proteins, lipids, and polysaccharides, as well as minor biologically active components, such as drugs, hormones, and toxins. The highest specificity is provided by the antibody-antigen interaction (which is called immunochromatography), which has been applied in food analysis to detect small concentrations of aflatoxins in peanuts. For even more demanding separations, new molecularly imprinted polymers are being synthesized and used to perform chiral and affinity separations.

As for sample preparation, it is widely accepted that this is one of the most important steps in warranting the quality of the analysis. This step becomes critical when analyzing organic substances in complex matrices like foods. In most cases, clean-up and concentration of the analytes is required prior to separation using LC. Among the useful sample preparation techniques, solid-phase extraction (SPE) is probably the most widely used. SPE is based on the selective retention of the compounds of interest on a sorbent placed in a disposable extraction minicolumn (or cartridge). This technique has been developed to replace classic liquid-liquid extraction and adsorption-based cleanup methods. By using this sample preparation method, interfering compounds can be removed and the analytes of interest enriched. To cover a wide range of analytes, several sorbents of polar, nonpolar, ionic, and polymeric materials can be used. SPE has been widely used in food analysis as a sample preparation or cleanup procedure prior to analysis using LC; among the compounds that have been extracted from foods are aromatic amines formed during heating, insecticides in fruits, fat contained in cereals, anthocyanins in plants, and pesticides in milk.

An extraction technique that has also been used mainly for fatty compounds (such as lipids and fat-soluble vitamins) is supercritical fluid extraction (SFE). SFE uses compounds that are held at

pressures and temperatures above their critical parameters, providing some advantages such as a reduced use of organic solvents, the possibility of tuning the selectivity of the extractant simply by changing the pressure or the temperature of the supercritical fluid, a reduced extraction time (because of the higher diffusivity associated with the supercritical fluids), higher quantitative yields (recoveries), and lower cost per extraction. Also important in terms of food sample preparation is the ability of SFE to be performed at low temperatures using a nonoxidant medium ( $\text{CO}_2$ ), which allows the extraction of thermally labile or easily oxidized compounds.

## Sugars (Carbohydrates)

Carbohydrates can be considered a major source of energy for the human body and on account of their diverse functional properties (considering the totally soluble carbohydrates such as glucose, fructose, galactose, lactose, maltose, and sucrose along with starch, gums, and pectins, among others) are used in the food industry as sweeteners, to enhance viscosity, acceptability, and palatability. Also, through well-known reactions induced by heating, reducing sugars can produce aromas and pigments. There is a need to monitor carbohydrates levels in food to predict their activity (also associated with human health) and to control the properties of foods. To determine quantitatively their content is also crucial for specially formulated foods (low-calorie, dietetic, suitable for diabetics, and with no lactose (in specially formulated milks)).

Prior to analysis by LC, carbohydrates can be extracted from food with water at a low temperature (to avoid risk of hydrolysis of oligosaccharides). After extraction, the crude aqueous extract should be cleaned up, usually by adding a volume of an organic solvent such as acetonitrile or by using a solid-phase cartridge.

Considering the wide range of molecular weights and types of carbohydrates, it is not possible to find a single LC method to cover all the applications. On the other hand, nearly all chromatographic modes can be used in separating carbohydrates. For example, LC analysis on chemically bonded amino, diol, or cyano groups have been used for separation of groups of monosaccharides and oligosaccharides. To achieve the desired separations, aqueous acetonitrile is used as a mobile phase, and the amount of water depends on the resolution needed. Reversed-phase (RP)-LC using  $\text{C}_{18}$  columns and using water as the mobile phase can also be employed to separate sugars with a different number of saccharide units.

Refractive index detection is normally used, but no gradient elution is allowed; therefore, new detection strategies are needed when challenging separations must be performed. In this sense, short-wavelength ultraviolet (UV) absorption (between 180 and 200 nm) can be used, but high-purity solvents are required. In order to overcome this problem, a derivatization reaction forming UV derivatives absorbing at higher UV wavelengths or fluorescent derivatives is carried out. Recently, a new detection device has been studied that is based on mass detection (evaporative light scattering detection (ELSD)). ELSD offers some advantages in terms of gradient compatibility, flat baselines, and improved peak shapes and resolution for mono- and oligosaccharides with a certain degree of polymerization (up to 22).

Nevertheless, the most common method of analyzing carbohydrates from foods is through ion exchange chromatography (IEC) using strongly or weakly basic anionic resins or cationic resins. IEC is often combined with amperometric detection, which allows electrochemical detection of sugars. The detection mechanism involves the oxidation of the sugar in an electrode (i.e., platinum or nickel-chromium (80:20) alloy). This type of detection has been proved to be very sensitive, allowing, for example, the analysis of disaccharides and oligosaccharides present in honey as minor components. **Figure 1** shows an example of a separation of oligosaccharides (maltodextrines) found in enteral formulas using IEC with amperometric detection.

Size-exclusion chromatography (SEC) has been applied to separation of sugars, particularly when the mixture contains sugars with a different number of saccharide units. In this sense, different methods have been developed for routine analysis of glucose, fructose, and sucrose in fruit juices; the analysis time is less than 8 min. In these separations, not only the molecular weight but also the molecular volume (spatial configuration) is taken into account. Two packing materials have been used, one based on a polystyrene polymer with an exclusion limit of  $\sim 1000$  and another one on a sulfonated monodisperse resin-based column in protonated form. Both systems allow the complete separation of small carbohydrates and also of some sugar alcohols such as mannitol, sorbitol, and xylitol.

## Vitamins

The nutritional role of vitamins is crucial to human health, and analytical methods have been developed in order to attempt complete separation of the different types of vitamins. The interest in vitamin

analysis is related to different purposes: implementing regulatory enforcement, checking compliance with nutrient labeling regulations, providing quality assurance for supplemented products, studying changes in vitamin content attributable to food processing, packaging, storage, etc. At present, LC is the method of choice, but the results are dependent on the extraction method used prior to chromatographic separation. Usually, vitamins are difficult to analyze because they are thermally labile compounds, readily oxidized by heat, oxygen, or UV light and, at the same time, are present in foods as minor components with physicochemical properties similar to those of the major compounds. LC offers some advantages for vitamin separation such as operation at low temperatures in the absence of light and oxygen, short exposure to UV light during detection, short analysis times, and the possibility of using selective detectors that allow simplification and shortening of the sample preparation step. In this article, fat-soluble and water-soluble vitamins will be discussed separately.

### Fat-Soluble Vitamins

The fat-soluble vitamins can be divided into four different groups, based on biological activity: vitamin A (retinol and carotenoids), vitamin D (cholecalciferol and ergocalciferol), vitamin E (tocopherols and tocotrienols), and vitamin K (phyloquinone and menaquinone), all of which may be present in a number of closely related forms.

**Vitamin A** Naturally occurring sources of vitamin A provide different forms of vitamin A (retinol, retinyl esters, and retinaldehyde) and provitamin A carotenoids. An adequate intake of dietary vitamin A is essential for normal vision, growth, functioning of the immune system, etc. All natural sources of vitamin A are derived from provitamin A carotenoids, which are synthesized exclusively by higher plants and photosynthetic organisms. The synthetic retinyl acetate or retinyl palmitate is used to supplement foods with vitamin A; unless knowledge of the ester form is important, the food is saponified to liberate free retinol prior to analysis; after saponification, an extraction step is needed. Sometimes (such as for the case of fortified milk) total vitamin A can be extracted directly using hexane and injected into the LC system.

Retinol can be chromatographed on normal-phase or RP columns, the latter being more appropriate when the sample extracts contain small amounts of triglycerides (after saponification). Different LC methods allow separation of various isomers such as the *cis-trans* retinol forms. Although retinol and

**Figure 1** High-performance anion exchange chromatography separation of (A) standard solution of maltodextrins and (B) enteral formulation. Column, Carbowac PA-100 (250 × 4 mm); mobile phase, gradient from water at pH 5.8 (mobile phase 1), 1 mol l<sup>-1</sup> sodium acetate (mobile phase 2), and 500 mmol l<sup>-1</sup> sodium hydroxide (mobile phase 3). Gradient program: mobile phase 1, constant at 57% from 0 to 6.5 min, then reduced to 42% at 31.5 min; mobile phase 2, constant at 10% from 0 to 6.5 min, then increased to 25% at 31.5 min; mobile phase 3, constant at 33% from 0 to 31.5 min; 1 ml min<sup>-1</sup>. Amperometric detection (gold electrode): pulse potentials for  $E_1$  of 0.05 V,  $E_2$  of 0.75 V, and  $E_3$  of -0.15 V were applied for duration times  $T_1$  of 0.4 s,  $T_2$  of 0.2 s, and  $T_3$  of 0.4 s. Peaks from G1 to G11 maltooligosaccharides. (Reproduced with permission from Moreno FJ, Olano A, Santa-Maria G, and Corzo N (1999) Determination of maltodextrins enteral formulations by three different chromatographic methods. *Chromatographia* 50: 705–710.)

retinyl esters exhibit native fluorescence, the quantum efficiency is low, and UV detection is commonly used in most LC systems (the wavelength of maximum absorbance is 328 nm).

**Vitamin D** Vitamin D ( $D_2$  or  $D_3$ ) is derived from UV irradiation of sterols. An adequate supply of vitamin D is essential in the prevention of rickets in children and of osteomalacia in adults. Dietary sources of vitamin D are essential for those people with inadequate skin exposure to sunlight. Vitamin D is present in foods only at trace levels. Because its physicochemical properties are similar to those of other lipid components present at higher levels, extensive sample preparation is needed prior to LC analysis. Saponification is mandatory for foods with high triglyceride (TG) content, followed by extraction using organic solvents. Further purification is usually needed to remove compounds such as sterols, carotenoids, and other constituents of the unsaponifiable fraction that could interfere in the LC determination of vitamin D. A wide variety of cleanup techniques have been used, including sterol precipitation, thin-layer chromatography (TLC), open-column chromatography, and SPE. Vitamins  $D_2$  and  $D_3$  can only be separated on RP columns using methanol:water or methanol:acetonitrile as the mobile phase. Detection is performed at 264 nm, providing enough sensitivity for detection in fortified foods and in those foods rich in vitamin D.

**Vitamin E** Vitamin E is found in vegetable oils and other food products such as nuts, seeds, and fruits in eight forms, four with saturated side-chains (tocopherols) and four with unsaturated side-chains (tocotrienols). Vitamin E plays an important role as a lipid antioxidant in stabilizing subcellular membranes. The different forms ( $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ ) are commonly found in the above natural products, but their biological activities differ from one another. Thus it is necessary to separate completely the various forms to obtain an assessment of the total activity. Direct solvent extraction or saponification can be used, depending on the food matrix. Oils and fats can be simply dissolved in hexane and analyzed directly using normal-phase LC with either silica or polar-bonded stationary phases. Under these conditions, the eight forms of vitamin E can be isocratically separated (Figure 2). Since RP-LC is not capable of separating  $\beta$ - and  $\gamma$ - isomers, it can only be used to determine the total  $\alpha$ -tocopherol after sample saponification. Fluorescence detection is commonly used on account of the strong natural fluorescence provided by tocopherols and tocotrienols, this type of detection having a high sensitivity and selectivity

**Figure 2** HPLC of vitamin E. (A) Standards of vitamin E vitamers. Column, 5  $\mu$ m Supelcosil LC-Si (250  $\times$  4.6 mm inner diameter); mobile phase, isooctane/ethyl acetate (97.5:2.5), 1.6 mL min<sup>-1</sup>; fluorescence detection, excitation 290 nm, emission 330 nm. Peaks: 1,  $\alpha$ -tocopherol; 2,  $\alpha$ -tocotrienol; 3,  $\beta$ -tocopherol; 4,  $\gamma$ -tocopherol; 5,  $\beta$ -tocotrienol; 6,  $\gamma$ -tocotrienol; 7,  $\delta$ -tocopherol; 8,  $\delta$ -tocotrienol. (B) Saponified rice bran sample. Chromatographic conditions as in (A) except for the mobile phase, isooctane/ethyl acetate/2,2-dimethoxypropane (98.15:0.90:0.85:0.1). (Reproduced from AOCS Press.)

against other lipidic material present in the sample. Fluorescence detection is performed using 290 nm (excitation) and 330 nm (emission) for tocopherols and tocotrienols. UV absorbance (at 280 nm) has also been used with enough sensitivity, and electrochemical detection has provided the highest sensitivity, allowing the detection of low picomoles of vitamin E in human plasma.

**Vitamin K** Vitamin K exhibits an important anti-hemorrhagic activity, which has increased the interest in developing analytical methods to determine its content in foods. The sample preparation includes various steps such as enzymatic hydrolysis and cleanup using SPE cartridges. Normal-phase LC and RP-LC have been used to separate vitamin K in conjunction with UV detection at 270 nm; fluorescence detection can be used only after phyloquinone has been converted to the corresponding hydroquinone after electrochemical or chemical reduction.

### Multiple Fat-Soluble Vitamins

Recent developments have been directed toward the simultaneous determination of multiple vitamins in foods. Separation of vitamins A, E, D<sub>2</sub>, and D<sub>3</sub> in lacteal matrices has been performed using RP-LC with methanol:water as the mobile phase and UV detection at 265 nm (or at the wavelength of maximum absorption of each individual form), after exhaustive saponification. Normal-phase LC has also been used to analyze multiple fat-soluble vitamins in seed oils after extraction or even direct injection of the sample prior to analysis. UV detection has also been used. Sometimes a combination of two detection systems such as UV-visible detection and fluorescence have been used to, for example, determine, respectively, the carotenoids and fat-soluble vitamins in foods.

### Water-Soluble Vitamins

In general, the methods available for water-soluble vitamins are less successful for real samples than those described for the fat-soluble vitamins. The problems are, in general, related to sample preparation prior to LC analysis since naturally occurring vitamins are often bound to other food constituents such as carbohydrates or proteins.

**Vitamin C** In food, vitamin C exists as two vitamers with equivalent biological activities: l-ascorbic acid (AA) and its oxidation product, dehydro-l-ascorbic acid (DHAA), while the stereoisomer, iso-ascorbic acid, has very low activity. In addition to their known activities as vitamins, their role in other health-promoting functions such as prevention of cancer, heart disease, hypertension, etc. is at present under investigation. The most important problem encountered in vitamin C analysis is the lack of stability and ease of oxidation that makes it necessary to use extraction procedures that avoid degradation; usually acids (metaphosphoric, trichloroacetic, etc.) are employed along with metal chelators such as ethylenediaminetetraacetic acid. Vitamin C can be analyzed using RP-LC (with C<sub>18</sub> columns) using water at low pH values (acidified with sulfuric acid or different buffers). Detection is performed through UV absorption at 254 nm when AA has to be detected. DHAA has its maximum absorbance between 210 and 230 nm, and therefore it is susceptible to interferences with different natural food constituents. Fluorescence detection (after derivatization with o-phenylenediamine) is often used to attain maximum sensitivity.

**Vitamin B<sub>1</sub>** In food, vitamin B<sub>1</sub> (thiamine) exists as four vitamers, the nonphosphorylated form,

thiamine (predominating in plants), and its phosphorylated esters (monophosphate, pyrophosphate, and triphosphate), which are the principal forms in animal products. Thiamine deficiency has been associated with beriberi disease. Extraction of vitamin B<sub>1</sub> includes acid hydrolysis to release vitamers from food matrices, although sometimes enzymatic hydrolysis is used to remove excess starch or protein in the matrix. Further cleanup is performed through ion exchange column chromatography or SPE on C<sub>18</sub> cartridges. Separation can be performed using RP ion pair chromatography. Detection in real food samples is done using a fluorescence detector (excitation 365–375 nm and emission 425–435 nm) after online or offline derivatization with alkali potassium hexacyanoferrate(III) to convert thiamine to thiochrome. UV detection has lately been rejected because of the interference of other peaks corresponding, for example, to nucleic acids.

**Vitamin B<sub>2</sub>** Food contains three B<sub>2</sub> vitamers, riboflavin and its two coenzyme forms, flavin mononucleotide and flavin adenine dinucleotide, which are the predominant vitamers in foods and are usually bound to proteins. Their analysis usually takes place after extraction with dilute mineral acids with or without enzymatic hydrolysis of the coenzymes (which is necessary to convert all forms to riboflavin and to quantify them as total riboflavin). The extracts may be purified using SPE with C<sub>18</sub> cartridges. All the operations performed prior to analysis need to be done under subdued lighting to avoid decomposition of riboflavin upon exposure to light. RP chromatography with C<sub>18</sub> columns is used along with fluorescence detection (excitation, 440 nm; emission, 520 nm).

**Vitamin B<sub>3</sub>** Vitamin B<sub>3</sub> (niacin) has different physiologically active forms, nicotinic acid, nicotinamide, and their coenzymes, which are very stable at ambient temperature. Usually acid or alkaline hydrolysis are used to convert nicotinamide to nicotinic acid for quantitation of both vitamers as nicotinic acid; the first treatment (acid) is used to quantitate biologically available niacin, while alkaline hydrolysis provides an estimate of the total niacin content. Nicotinic acid has been analyzed using ion exchange or RP chromatography with amino columns. Detection is performed with UV absorbance at 254 nm.

**Vitamin B<sub>6</sub>** Pyridoxine is the principal vitamer of vitamin B<sub>6</sub> in plants products, while pyridoxal phosphate is the predominant form in animal-based foods. The analysis of vitamin B<sub>6</sub> is quite complex due to the presence of six possible vitamers of

different structures. Sometimes enzymatic hydrolysis is used to convert phosphorylated vitamers to simple forms. They are light sensitive, and therefore analysis must be performed under subdued lighting. LC has the extraordinary capability of separating vitamers (including glycosylated ones) using  $C_{18}$  columns and low-pH (2.2) mobile phases with alkane sulfonates to favor ion pairing. Fluorescence is used as detection method because of its increased sensitivity and specificity relative to UV absorbance; nevertheless, even if vitamers fluoresce naturally in slightly acidic to neutral solutions, postcolumn derivatization with, for example, monobasic potassium orthophosphate is often used to adjust the pH for enhanced fluorescence sensitivity of  $B_6$  vitamers.

**Folacin** Folacin gives rise to a large number of related compounds having the same basic structure as folic acid but differing in the state of reduction and the number of glutamate residues. Folacin vitamers are sensitive to heat, oxygen, light, and extremes of pH. Their analysis is complicated by the low levels at which vitamers occur in food, their lack of stability, and the multiplicity of forms of naturally occurring vitamers. Extraction takes place after homogenization in a neutral or mildly acidic solution and usually contains one antioxidant such as ascorbic acid. Sometimes folacin in polyglutamate forms is enzymatically deconjugated to the corresponding monoglutamates prior to quantitation. Sample cleanup is accomplished by means of SPE on anion or cation resins, although affinity chromatography using a folate-binding protein isolated from milk has also been used. LC using ion exchange or RP ion pair chromatography is the method of choice, but due to the complexity of folacin vitamer analysis, at present there is no single LC method to achieve such separation. UV absorption is often sufficient to allow detection at the levels at which folic acid is added in fortified foods; if more sensitivity is needed, fluorescence detection can be used simply by using an acidic pH (pH value of 2.3) or after postcolumn oxidative cleavage of a pterin fragment.

### Multiple Water-Soluble Vitamins

At present, much effort is being devoted to simultaneous separation and detection of water-soluble vitamins. Undoubtedly, multiple water-vitamin analysis using LC as a separation method is effective with RP ion pair chromatography with acidified methanol or acetonitrile:water as the mobile phase. Detection is performed using combined systems such as UV absorbance and fluorescence systems, depending on the vitamins to be determined. Analysis in real food

samples requires complex sample preparation with multiple steps (extraction, hydrolysis, oxidation, cleanup, etc.) that are reduced when synthetic preparations have to be analyzed.

### Amino Acids, Peptides, and Proteins

The importance of amino acids, peptides, and proteins is widely known and it arises from different aspects ranging from an important role in human nutrition and health to different technological functions that can widely influence the quality of food products (mainly for peptides and proteins). Therefore, their analysis is crucial not only from the nutritional point of view (for example, to warranty and verify the content of an specific amino acids) but also for product quality assessment and product development (where information about the composition of the protein fraction is mandatory). Also important is assessment of the authenticity of foods through enantiomer separation and identification.

Amino acid analysis has a different approach, in terms of sample preparation, if free or total amino acids have to be determined. For amino acids bound to proteins, it is necessary to liberate them, using acid hydrolysis or acid digestion with microwave heating, prior to chromatographic analysis. A clean-up step is always needed to remove interferences and/or to concentrate the sample. Usually sample clean-up is performed using SPE with different resins (cation exchange) or  $C_{18}$  cartridges that can retain lipids and large proteins and allow elution of free amino acids.

One of the most commonly used methods in the separation of free amino acids using LC is ion exchange chromatography (cation exchange resin), which in its new format of small particles and pellicular packings has improved both the resolving power and the analysis time. Detection is performed through UV absorption after postcolumn reaction with ninhydrin ( $\lambda_{\max} = 570 \text{ nm}$ ) or *o*-phthalaldehyde (OPA), which allows the detection limit to be decreased to 5 pmol. RP-LC can also be used after precolumn derivatization with OPA, phenylisothiocyanate (PITC), or 9-fluorenylmethyl chloroformate (FMOC), among others. A typical derivatization scheme of an amino acid with FMOC is shown in **Figure 3**. Derivatization allows spectroscopic detection of amino acids while increasing their degree of hydrophobicity (and subsequently their retention), allowing their separation using RP-LC.

Separation of chiral amino acids has become very important for assessing authenticity: only L-amino acids seem to have a natural origin and D-isomers

**Figure 3** An example of a typical derivatization scheme of amino acids with Fmoc-Cl.

cannot be utilized by humans, so that the associated proteins have a decreased digestibility. Enantiomeric separation of the d- and l-amino acids can be carried using three different approaches: precolumn derivatization with a chiral agent followed by separation of the resulting diastereomers on regular RP columns, direct separation of underivatized enantiomers on a column with a chiral bonded phase (such as the Pirkle column), and using a chiral crown ether added to the mobile phase.

Peptide analysis requires an exhaustive sample preparation consisting of two steps: sample extraction and removal of proteins, usually by ultrafiltration, which allows fractionation of peptides at the same time. Further clean-up through SPE with C<sub>18</sub> cartridges is often necessary. Peptide LC analysis can be done using RP columns with ion pairing agents such as trifluoroacetic acid (TFA), IEC, and SEC. Detection is performed through UV absorption (for aromatic amino acids and tyrosine and tryptophan) and, more commonly, after derivatization with dansyl chloride or PITC (for primary and secondary amino groups). One of the most important advances in peptides detection has been the online coupling of LC with mass spectrometry (MS) through an electrospray ionization (ESI) interface, which allows the identification of high-molecular weight biopolymers generating multiple charged molecular ions, being, at the same time, compatible with liquid mobile phases. Matrix-assisted laser desorption/ionization coupled to a time-of-flight mass analyzer (MALDI-TOF-MS) has also been used for peptide analysis, allowing accurate determination of the mass of peptides and proteins with a high sensitivity (subpicomole range). The data obtained from the above-mentioned soft

ionization methods along with database searching have allowed the characterization of peptides of great biological significance and also their sequencing.

Separation of peptide stereoisomers can be accomplished using the same approach as for chiral amino acids, as mentioned before.

Proteins are often analyzed after isolation using different systems such as dialysis, ultrafiltration, or protein precipitation with organic solvents or addition of high concentrations of salts. Once isolated, proteins can be analyzed using RP-LC, IEC, and SEC. Recent studies have shown the possibility of fast separation of proteins using LC with pellicular packings, perfusion packings, and monolithic columns. These are different approaches to the same problem, which is the low diffusivity of some molecules into the pores of conventional packings, which ends up with a dramatic band broadening and, therefore, with a loss of efficiency. Pellicular packings consist of nonporous sorbents with a fluid impervious core that allow rapid analysis of proteins due to the suppression of diffusion inside the pore structure. Perfusion packings are based on packing materials with different pores, the throughpores (>500 nm) and a network of smaller pores (30 nm < diameter of pores < 70 nm) branching from the throughpores; this structure allows a huge increase in flow rate without loss of resolution. The most recent approach consists of using monolithic columns, which are agglomerates of polyacrylamide particles, and silica-rod columns: these columns provide a high efficiency and better permeability than the conventional columns used in LC, allowing also a higher flow rate and therefore reducing the total analysis time. Because of the flat plate height versus flow velocity curves at high velocity values, it is possible to work at higher flow rates without losing efficiency. These columns can be used for rapid purification of proteins.

UV absorbance and fluorescence and, lately, LC-MS are the most commonly means of detecting proteins. LC-ESI-MS and MALDI-TOF-MS have largely improved our knowledge of the primary structure of proteins and have become the methods of reference in both food control and food research laboratories.

## Lipids

Lipids are involved in many important biological processes in humans, and since the absorption and metabolism of numerous lipids are closely related to several diseases, analysis of lipids has grown greatly in recent years. Diverse definitions for lipids can be considered, but all of them include fatty acids and

their derivatives and substances related biosynthetically to these compounds; other definitions include also carotenoids, terpenes, and other classes of compounds. As components of oils and fats, lipids are almost ubiquitous food ingredients, with an important role in nutrition and the taste and functional properties of the final product.

The main area of application of HPLC in lipid analysis is the determination of larger molecules like triglycerides and phospholipids, while the analysis of smaller lipid classes like sterols and fatty acids is usually carried out using gas chromatography (GC), though it is possible to analyze these molecules using LC too. The subject can be divided in two topics: separation of simple lipid classes from a lipid fraction and separation of the individual components, like the different sterols of a specific fraction.

Sample preparation for analysis of lipids poses few problems. If the sample is liquid, often it is not necessary to extract or fractionate the food, and even direct injection of liquid samples such as oils can be done. For solid foods, a simple extraction with a nonpolar solvent or mixture of solvents is enough to isolate the fat containing triglycerides, followed by a simple cleanup if needed, before injection into the LC. For detection, the refractive index has been traditionally used for triglyceride analysis with isocratic elution, though the separation of lipids using RP-LC with gradient elution excludes the use of refractive index detectors, and mass detectors or light-scattering detectors are being regularly used to obtain better sensitivity than with UV detection.

The separation of simple lipid classes from a lipid fraction aims to obtain distinct fractions of sterol esters, triacylglycerols, diacylglycerols, free sterols, free fatty acids, monoacylglycerols, and wax esters. There are numerous methods for lipid class separation, traditionally employing adsorption chromatography with silica gel columns, with increasing use currently of bonded phases such as the nitrile, diol, and polyvinylalcohol phases and of ELSD. These bonded phases give much better reproducibility of retention times than do the usual silica gel columns. Nevertheless, refractive index detection with silica gel columns and isocratic elution is still frequently employed for routine applications.

The separation of triglycerides using partition chromatography can be done both in RP and normal-phase columns. RP columns have given better results with nonaqueous mobile phases (for instance, acetonitrile:acetone), which allow separation of triglycerides according to the equivalent carbon number. Normal-phase silica columns have been used for analysis of triglycerides, which is a classical application of this type of column. The main

drawbacks are the problems of reproducibility and time of stabilization. Oxidized triacylglycerols (monomers, dimers, and polymers) are separated using SEC with two columns in series and refractive index detection after isolation of the polar fraction from fats using SPE.

The preferred method for analysis of free fatty acids is GC, while TLC and HPLC can be used to isolate the fatty acid fraction. The alternative determination using HPLC needs fatty acid derivatives to be prepared using a chromophore to allow detection using the most sensitive fluorescent detector. Many examples of different derivatives can be found in the literature.

Analysis of the components of other fractions of simple lipids like free sterols, sterol esters, and wax esters by means of HPLC has some drawbacks, and it is usually performed using high-temperature GC. However, the most remarkable field of application of HPLC is the analysis of oxidized sterol and their esters, of biological interest, that used to be performed earlier using RP-LC with postcolumn fluorometric detection and is nowadays be carried out using LC coupled to MS, providing structural information on these complex derivatives.

## Minor Components of Food

A developing area of analytical development in HPLC is the determination of several groups of minor food components, like flavonoids and polyphenols in general, xanthophylls, and other carotenoids. Most of them have important bioactivities and have stimulated much interest in food and nutrition studies.

These food components have the common property of being labile and so are degraded by light, heat, or oxygen, which limits the sample extraction and cleanup, and especially its great complexity, with dozens (or even hundreds) of very similar components or isomers, which sometimes makes it extremely difficult to separate the components of each family in the sample. An additional problem is the lack of standard compounds for most of them, which makes the identification very complicated. The difficulty is usually overcome by coupling LC with MS, or with MS/MS, to determine the structure of the separated compounds.

### Phenolic Compounds

Phenolic compounds have been traditionally of interest due to their contribution to the color and taste of food, but nowadays the main interest in their determination is the proven bioactivity of many of

them, which includes beneficial functions such as antioxidative, antimicrobial, and anticarcinogenic activities. The phenolic family includes thousands of compounds, from simple (monocyclic) phenolic acids to flavonoids, which can be divided into many classes (flavone, flavanone, flavonol, anthocyanin, isoflavone, etc.), present as aglycone or as glycoside. An important group of polyphenols is that of the anthocyanins, the largest group of water-soluble pigments in nature, responsible for the intense color of many fruits and flowers. Because of their chemical structure and polarity, RP-LC is the most regularly used technique in the analysis of polyphenols.

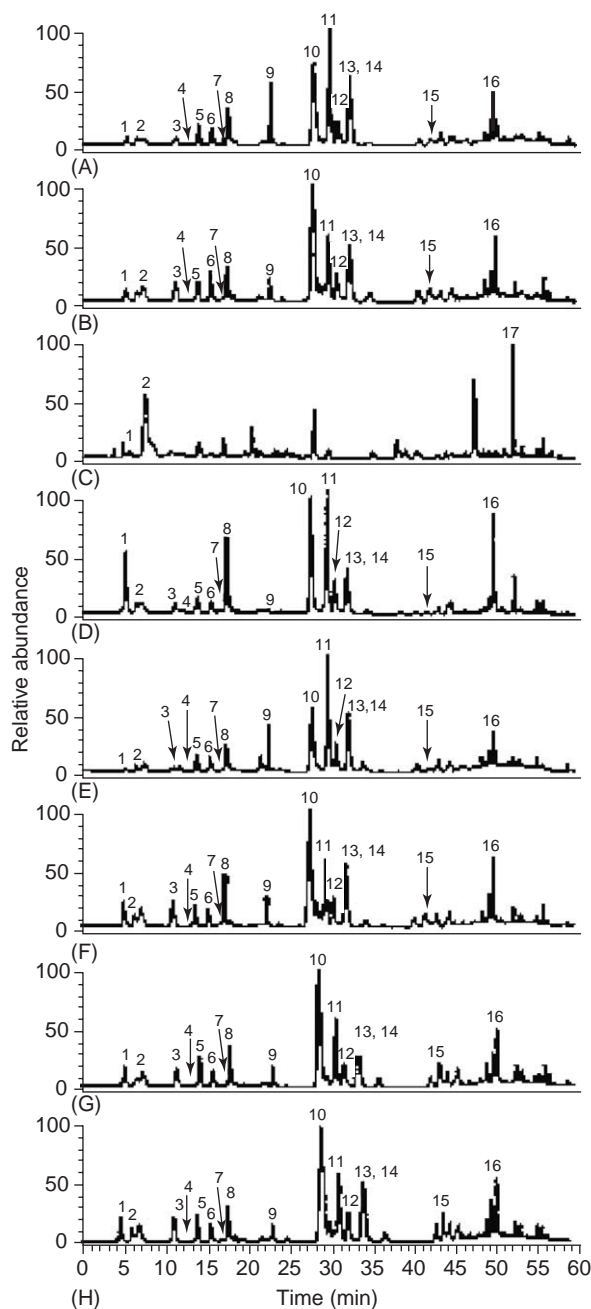

There are countless methods of analysis of phenolic compounds in the literature, the majority of them employing  $C_{18}$  columns with binary gradients (with acetonitrile or methanol) in aqueous RPs. Frequently, the ionic strength and, especially, the acid pH of the mobile phase must also be optimized. Many types of detector have been used for this application, with UV detection (or, more conveniently, detection using a photodiode array detector) being the most commonly used form of detection and with an increasing number of methods that use LC-MS with ESI. An example of the analysis of phenolic compounds in ethanolic extracts of propolis (a natural substance collected by honeybees from buds and exudates of certain trees and plants) of different geographical origin using LC-MS is shown in Figure 4.

### Carotenoids

The analysis of carotenoids, including carotenes (without oxygen) and the oxygenated derivatives xanthophylls, poses a difficult challenge to

the analyst, mostly due to the great variety of carotene isomers including *cis-trans* isomers, cyclic and acyclic isomers, and the number of oxygen functions, which can produce hundreds of combinations (where lycopene,  $\beta$ -carotene, zeaxanthin, lutein,  $\beta$ -cryptoxanthin, and violaxanthin are just some known examples), and the very low oxidative stability of carotenoids once they have been isolated.

Carotenoids can be analyzed using normal-phase LC or RP-LC, but RP-LC is preferred because carotenes are strongly retained and the separation of  $\alpha$ - and  $\beta$ -carotenes is easily achieved. Since carotenes

**Figure 4** HPLC chromatograms of ethanol extracts of propolis of various geographic origin. are only sparingly soluble in typical RP solvents (methanol or acetonitrile), different mixtures containing acetonitrile/dichloromethane/methanol (70:20:10) or methanol/chloroform have been successfully used along with octadecyl silica (ODS) columns to separate different carotenoids and/or isomers. Polymeric stationary phases (especially C30- and C34-bonded phases) have distinct advantages over the common C<sub>18</sub> material for separation of similar carotenoids, though in these cases control of the temperature of analysis is critical.

Detection has been usually accomplished by light absorption in the visible region ( $\lambda_{\text{max}}$  453 nm for  $\beta$ -carotene), while LC-MS examples for identification of complex samples of carotenoids are becoming common.

### Other Pigments

Chlorophylls and their derivatives in food are separated using HPLC with great advantages compared with other analytical techniques, and consequently RP-LC with spectrophotometric detectors is the most used technique for their analysis. On the other hand, several researchers have developed methods to analyze simultaneously chlorophylls and carotenoids of fruits and vegetables in a single run using RP HPLC with mobile phases in gradient and ODS columns. The determination of other pigments in food is usually less complex than in the case of anthocyanins or carotenoids, mainly because of the limited number of components of other groups like betalains (natural pigments) or azo dyes (synthetic), and routine HPLC applications for them can be found in the literature.

### Food Contaminants

The growing concerns regarding food safety have made the analysis of food contaminants an area of intense development in recent years, with a focus on chromatographic techniques, where LC has an essential role. The number of possible food contaminants grows without limit, including mycotoxins, antibiotic residues, and other potentially dangerous chemicals.

Analysis of pesticide residues is usually performed using GC, and the main field of application of LC is the simultaneous detection of very different pesticides in a single analysis, due to the lack of limitations of volatility or stability compared with GC. Compared with other analyses of minor components of food, determination of residues in food needs lower detection limits and, usually, laborious sample preparation and fractionation before the LC separation can take place.

Separation of organochlorine and organophosphorus pesticides residues is mainly performed in RP-LC columns with water and acetonitrile or methanol or both. The usual detector is a UV detector or a diode array detector, with a growing number of applications that use MS with APCI interface.

The analysis of mycotoxins, toxic substances produced by some fungi, is essential to guaranteeing the safety of foods such as cereals, nuts, oilseeds, and spices since the discovery of their significance to human health. The main mycotoxins, like aflatoxins and ochratoxin A, are determined using HPLC with octyl- or octadecyl-bonded phases and polar solvents such as methanol, acetonitrile, and water. For detection with the required sensitivity and selectivity, spectrofluorimetric detection is the most common method, with increasing use of mass spectrometric interfaces.

Another source of concern in food safety control is the increasing amounts of residues of veterinary drugs that can be found in foods. These drugs are mostly antibiotics of different structures, such as tetracyclines, macrolides, quinolones, sulphonamides, and  $\beta$ -lactams. The preferred analytical technique for antibiotic residue determination is HPLC, and specific methods for each family of antibiotics can be found in the scientific literature. Most of the published methods use RP columns with gradient elution. Every available detection method can be used, depending on the application, though MS is a powerful technique for the identification and confirmation of veterinary drug residues in food samples, and at the moment, LC-MS is the method of reference.

### Introduction

Liquid chromatography (LC) has been applied in the pharmaceutical industry almost from the inception of the technique and certainly through its adolescence up to its current mature status. Liquid chromatography in particular has grown along with the demands of the pharmaceutical industry because of its unique capabilities and strengths, including the obvious precision, accuracy, low levels of detection, selectivity (stability-indicating properties), robustness, versatility in terms of column and mobile phase chemistries and mechanisms of separation, and range of detection methods.

### Overview of Requirements

In order to understand the place of liquid chromatography in the pharmaceutical industry, the evolution of a drug in the drug development cycle should be briefly discussed first. Several of the major stages a drug passes through from discovery to commercialization of a dosage form and further, are outlined in **Table 1**.

From the synthesis of a drug onwards, its identity strength, purity, and quality are continuously assessed and monitored, commonly using chromatography. The organic chemist discovering the compound is likely to use analytical LC to study reaction progress and condition optimization in synthetic and isolation schemes. Preparative LC is also used at various stages of discovery to provide adequate quantities of purified intermediates to take to subsequent steps and quantities of purified products for pharmacological testing. When larger than laboratory scale quantities of bulk drug are required in chemical process development, pilot production scale and later, full production scale batches are prepared. The resulting drugs and intermediates are assayed by

analytical LC and similarly release-tested at later stages.

Analytical research department involvement with bulk drug LC methods development commonly begins during early toxicology and safety evaluation, when it is necessary to document dose administered in the vehicle used and stability of the drug in the vehicle over the dosing period. This soon leads to preclinical method validation studies for the bulk drug assay and for the development of an impurities assay, both of which receive full validation at the later time.

Metabolism, pharmacokinetics, and bioavailability studies, initially on a preclinical level but later after human testing is approved, are also supported by LC analytical methods of drug and metabolite levels determination in various biological fluids and tissues. These studies and those to support further toxicology testing are the subject of other articles.

Chromatographic studies in pharmaceuticals development departments generally begin with preformulation testing and evaluation of bulk-drug properties such as solid state and solution stability and degradation mechanisms. Dosage form development is monitored by LC stability studies on short-term and later formal long-term bases. LC analytical methods to support these latter studies and validation thereof are normally carried out in analytical chemistry departments.

Drug substance impurity profiling is conducted on several batches by high-sensitivity LC methods prior to Investigational New Drug application (IND) submission, while the number of batches increases substantially by New Drug Application (NDA) time. In addition, formal drug substance stability studies are conducted with potency and impurity level testing by LC as integral parts.

Once the product formula and process of manufacture are characterized, they are documented and sets of tests and specifications are compiled. Specific testing is used to release incoming raw materials and bulk drug as well as finished product. Here again in release testing, LC plays a major role. No matter what stage of development the drug has reached,

### Introduction

Liquid chromatography (LC) has been applied in the pharmaceutical industry almost from the inception of the technique and certainly through its adolescence up to its current mature status. Liquid chromatography in particular has grown along with the demands of the pharmaceutical industry because of its unique capabilities and strengths, including the obvious precision, accuracy, low levels of detection, selectivity (stability-indicating properties), robustness, versatility in terms of column and mobile phase chemistries and mechanisms of separation, and range of detection methods.

### Overview of Requirements

In order to understand the place of liquid chromatography in the pharmaceutical industry, the evolution of a drug in the drug development cycle should be briefly discussed first. Several of the major stages a drug passes through from discovery to commercialization of a dosage form and further, are outlined in **Table 1**.

From the synthesis of a drug onwards, its identity strength, purity, and quality are continuously assessed and monitored, commonly using chromatography. The organic chemist discovering the compound is likely to use analytical LC to study reaction progress and condition optimization in synthetic and isolation schemes. Preparative LC is also used at various stages of discovery to provide adequate quantities of purified intermediates to take to subsequent steps and quantities of purified products for pharmacological testing. When larger than laboratory scale quantities of bulk drug are required in chemical process development, pilot production scale and later, full production scale batches are prepared. The resulting drugs and intermediates are assayed by

analytical LC and similarly release-tested at later stages.

Analytical research department involvement with bulk drug LC methods development commonly begins during early toxicology and safety evaluation, when it is necessary to document dose administered in the vehicle used and stability of the drug in the vehicle over the dosing period. This soon leads to preclinical method validation studies for the bulk drug assay and for the development of an impurities assay, both of which receive full validation at the later time.

Metabolism, pharmacokinetics, and bioavailability studies, initially on a preclinical level but later after human testing is approved, are also supported by LC analytical methods of drug and metabolite levels determination in various biological fluids and tissues. These studies and those to support further toxicology testing are the subject of other articles.

Chromatographic studies in pharmaceuticals development departments generally begin with preformulation testing and evaluation of bulk-drug properties such as solid state and solution stability and degradation mechanisms. Dosage form development is monitored by LC stability studies on short-term and later formal long-term bases. LC analytical methods to support these latter studies and validation thereof are normally carried out in analytical chemistry departments.

Drug substance impurity profiling is conducted on several batches by high-sensitivity LC methods prior to Investigational New Drug application (IND) submission, while the number of batches increases substantially by New Drug Application (NDA) time. In addition, formal drug substance stability studies are conducted with potency and impurity level testing by LC as integral parts.

Once the product formula and process of manufacture are characterized, they are documented and sets of tests and specifications are compiled. Specific testing is used to release incoming raw materials and bulk drug as well as finished product. Here again in release testing, LC plays a major role. No matter what stage of development the drug has reached,

**Table 1** The drug development cycle

Discovery: organic, pharmacology	Drug substance characterization, salt selection, thin layer chromatography, preparative and analytical LC	
Chemical process development	Process improvement, intermediates characterization, impurities, solvent selection, scale-up	
Toxicology and safety testing	Preclinical Clinical	
Metabolism, bioavailability and pharmacokinetics	Preclinical Clinical	IND (CTA) Phase I Phase II Phase III
Environmental impact studies		
Preformulation studies	Solid state Solution state Compatibility	
Formulation studies	Laboratory scale, pilot scale	
Process improvement	Manufacturing	
Stability studies	Short-term, drug substance Long-term, drug product Clinical product Marketed product	
Tests and specifications development		
Drug substance	Release testing	NDA (MAA)
Excipients	Shelf-life testing	Submission
Drug product	In-process testing	Approval
Technology transfer	Manufacturing Quality control Process validation Cleaning validation	
Commercial production		
Marketed product	Line extensions, new package, new manufacturing site, new vendors	Phase IV

preclinical, clinical (Phases I–III) or commercial (Phase IV), release testing is required.

Technology transfer generally begins during Phase III clinical studies. This includes both transfer of the manufacturing process of drug substance and product and of testing procedures to specific company facilities or contract laboratories for implementation as chemical and commercial product sources.

Following approval to market the product, any change or upgrade in the process or reformulation of the product can require stability work and LC methods development to support studies. Any new manufacturing sites for bulk drug or drug product also need stability support. New vendors for packaging components or excipients must be qualified by Good Manufacturing Practice (GMP) requirements, which usually involves stability studies on product

manufactured with the changes. Product that is approved for marketing also requires formal stability studies, which are conducted to the extent of the proposed shelf-life aside from release testing. These also include LC analysis of product potency.

Other tests that require LC methods in the drug development cycle include assays for key process intermediates, in-process testing, cleaning validation studies, and compatibility testing. Synthetic process intermediates must be characterized structurally, by means of spectroscopy, but purity information and assays are applied as well with results supplied in regulatory filings. In-process testing may include an assay of activity in some pivotal step of processing the dosage form, although this is not always the case. These steps may be at a granulation stage prior to tableting or encapsulation or in a bulk solution stage

prior to filling. Cleaning validation studies are required as part of GMP procedures and these usually include testing at maximum sensitivity for the presence, or absence, of active components. Compatibility testing is commonly carried out on parenteral products that require mixing with available intravenous diluents (water for injection, normal saline, 5% dextrose, etc.). These are short-term stability tests that need drug assay and often impurities measurements conducted chromatographically. In addition, a significant portion of the activities of quality control departments on bulk drug, raw materials, and finished products involves LC measurements.

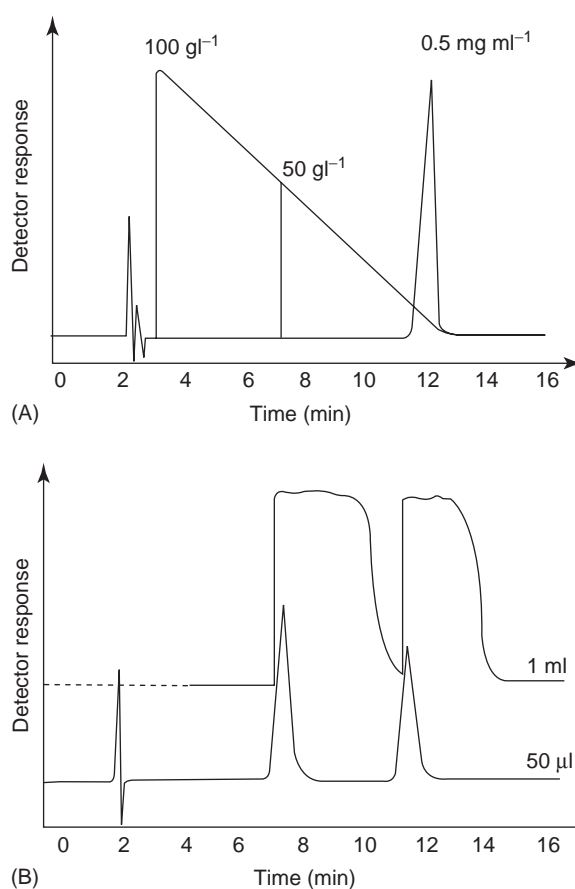

## Drug Substance Methods

### Preparative LC

In the synthesis of biologically active compounds, purification, isolation and identification procedures are necessary. The chromatographic methods that have traditionally been used by organic chemists (thin-layer chromatography (TLC), low-pressure open-column and flash chromatography) are supplemented with preparative LC. Major differences between preparative and analytical LC are column dimensions, mobile phase flow rates, and sample injection masses and volumes. Preparative column diameters often go from 8 mm to over 100 mm with lengths of 250–1000 mm. These large columns can require mobile phase flow rates of up to  $100 \text{ ml min}^{-1}$  and sample injection volumes up to several milliliters. Sample concentration can routinely run as high as hundreds of  $\text{mg ml}^{-1}$ . In the isolation of intermediates or final products in reaction schemes or of unknown impurities or related compounds, use is made of automatic fraction collectors and replicate injections.

Two different modes of operating preparative LC systems, touching bands and overlapping bands, were described along with optimization schemes for each in a summary paper (see bibliography). While production rates and yields can be balanced by an appropriate choice of sample size and flow velocity, preparative separations often use overload conditions. The results of concentration or sample volume overload on chromatographic peak shape are shown in **Figures 1A** and **1B**. Concentration overload will change a normal analytical-shaped peak into a fronted peak at earlier retention times, while sample volume overload will result in characteristic flat-topped peaks at later retention times than in analytical runs.

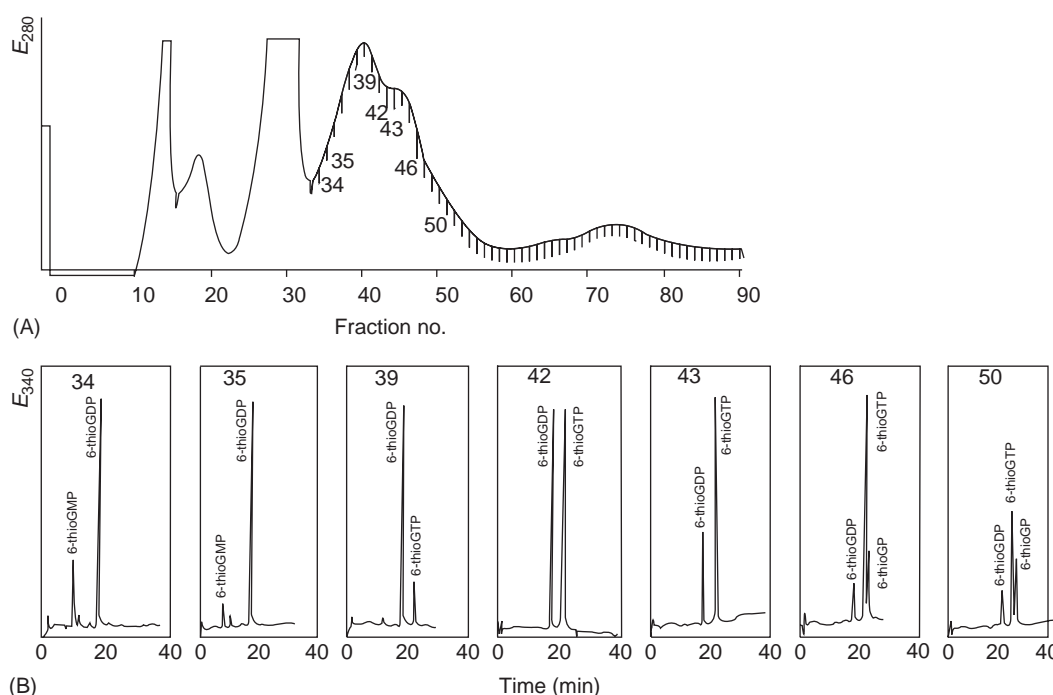

The use of low-pressure liquid column chromatography is an integral part of organic synthesis, with several recent examples described for pharmaceutically related compounds. For example, columns

**Figure 1** Preparative LC peak shapes resulting from (A) sample concentration overload and (B) sample volume overload.

packed with DEAE Sephadex A25 have been used to purify 6-thio-guanosine 5'-monophosphate, -guanosine-5'-diphosphate and -guanosine-5'-triphosphate from reaction mixtures with fractions collected and assayed by analytical LC as shown in **Figure 2**. The UV absorbance detector was set at 280 nm for the low-pressure separation, while LC of the collected fractions was monitored at 340 nm. It can be observed that 6-thioGTP reached a maximum content in fraction 43.

Prior to the routine use of mass spectrometry in the pharmaceutical laboratory, fraction collection in preparative LC was driven by UV detection. Every UV-active compound above a certain threshold setting will trigger fraction collection. While this method ensures nearly perfect capture of all analytes of interest, in many cases excess fractions are collected. Many commercial instrument companies have developed preparative LC systems that use mass spectrometry to detect and trigger the fraction collection. In this case, only the target molecule is selected, enabling higher throughput sample preparation. If target molecules do not respond in the MS, then

**Figure 2** (A) Elution profile of 6-thiopurines obtained on a low-pressure DEAE-Sephadex column showing times of 90 fractions collected. (B) Liquid chromatograms of seven collected fractions showing content of specific 6-thiopurines. GMP, guanosine-5'-monophosphate; GDP, guanosine-5'-diphosphate; GTP, guanosine-5'-triphosphate. other detection techniques such as UV or ELS can be added to the system.

### Impurities Testing

The second important aspect of drug substance liquid chromatographic analysis in the pharmaceutical industry, and one of great importance to the control of raw materials and stability of the drug, is that of impurities analysis. While continuous monitoring of drug substance purity is conducted in the development of a chemical synthetic process, it is also used in stability testing and release testing of bulk-drug lots. This latter information is required by the respective regulatory authorities in drug product submissions to show the lack of variation in purity profile between lots of drug substance produced at different sites by different manufacturing processes, and to show stability of the drug itself. Process impurities and degradation products along with structural analogs have been termed 'related substances'. In general, process impurities include trace substances resulting from the drug substance synthesis, trace side-reaction products, or contaminants not removed by the isolation and purification scheme. These should remain at a constant level or possibly decrease as the bulk drug is incorporated into a dosage form and tested on a stability program. Degradation

products, on the other hand, which are assayed using the same or similar methods to the drug substance purity method, can accompany the bulk drug at release as a process impurity. More importantly, they can arise by the usual instability reaction mechanisms over time: hydrolysis, oxidation, photolysis, isomerization, rearrangement, reduction, substitution, elimination, etc. These products must be investigated, isolated, identified, and monitored in stability protocols to provide sufficient data for filing to show that their levels are under control.

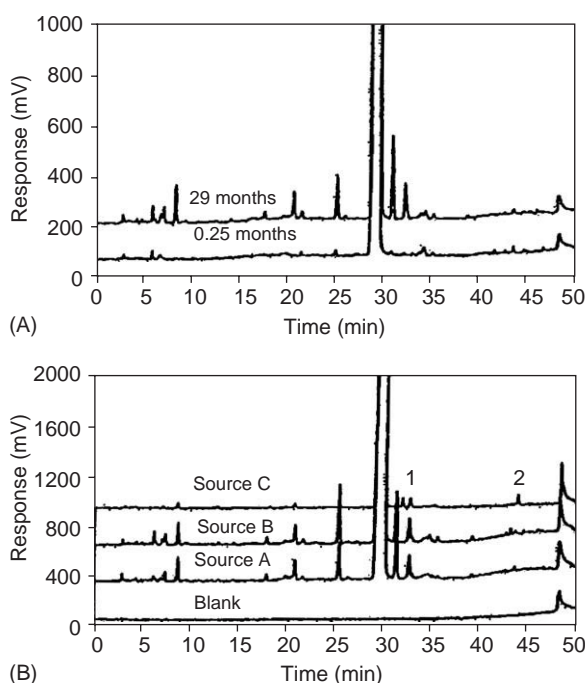

Regulatory authorities set various levels for individual and total impurities in both drug substance and drug product that must be reported and investigated. Usually >0.1% of the active component is set for measurement, with limits imposed for total and individual impurities in batch release of drug substance and possibly drug product as well. This testing is required in addition to the normal purity assay method, usually analytical LC, where specifications of  $\pm 1$ –2% are found for drug substance and drug product. Every pharmaceutical company must therefore be concerned with levels of impurities and degradation product in their compounds of interest and must have the required information on file both in house and with the regulatory authorities; however little of it has been published outside.

When the impurities or degradation products have been identified by spectroscopic means, their structure and often proof of structure are also included in the filing. The application of impurities information is in control of the synthetic process for the drug substance. In this way the homogeneity of the drug can be assessed as vendors of raw materials, reaction steps, recrystallization solvents, synthetic scale, and other process parameters are varied. The application of degradation product determination in drug substance and drug products will be further discussed in the section on stability below.

Several pharmaceutically relevant studies have been published that discuss impurity profiling by LC. The drugs ethynodiol diacetate, enalapril maleate, and piceurionium bromide were subjected to analysis of impurities utilizing diode-array detection with structure determination by spectroscopy. *E* and *Z* isomers of the 4-oestrene 17 $\alpha$ -ethynyl impurities, the *p*-tolyl analog and 2-dehydro-piceurionium were identified in these drugs, respectively. Related substances in the antibiotic cefaclor were measured using a reversed-phase gradient method with UV absorbance detection at 220 nm. Altogether, seven degradation products and 11 other process impurities were separated. Applications from this study in drug substance stability testing and in drug sourcing are illustrated in Figures 3A and 3B.

Among the related substances in many antibiotics are various structurally related components in the drug substance, the composite mixture of which is obtained in the synthetic or semisynthetic scheme and which gives rise to the drug efficacy. Control of the relative content of components is therefore necessary for these drugs. Test specification limits for the components are normally stated in terms of area percent of each, as maximum, minimum or a range of values for each or for the sums of several components. The types of components seen in these antibiotics were studied as impurities in the semisynthetic antibiotic clarithromycin, where detection limits of 0.1% w/w were found. Normalization factors were determined for each of 15 known related substances using ratios of the slope of linear calibrations for each substance to that for the reference impurity.

Routine impurities testing employs the use of HPLC with UV detection. However, this methodology requires additional testing to identify these analytes. By coupling HPLC to mass spectrometry, these impurities can be identified during the LC run. MS also offers a second confirmation (in addition to the retention time) as to the identity of the impurity.

## Preformulation Studies

Preformulation testing involves the physical chemical characterization of drug substances. This consists of testing on the drug in the solid state, on the drug in solution and on the drug in prototype dosage forms. Solid-state testing includes thermal (differential scanning calorimetry and thermogravimetric analysis) and microscopic (including hot-stage) particle size, surface area, solid volume, cohesivity-flow, and batch variation studies. Stability of the drug substance is studied in relation to heat, light and humidity stress. Spectral properties of the drug substance as measured in spectroscopy or physical chemistry sections using mass spectrometry, nuclear magnetic resonance or infrared spectrometry, etc., are not usually considered preformulation studies. Solution studies can be classified into solubility studies (pH/solubility, non-aqueous and intrinsic dissolution), stability studies (pH, photochemical, thermal, nonaqueous, mechanistic), and ionization constant, partition coefficient and solubility product determinations. Preformulation testing can also encompass compatibility testing between the drug and individual excipients or groups of excipients, or between mixed products as occurs in hospital settings where more than one intravenous

product can be mixed for administration to patients. Stability properties of the drug substance, prototype dosage forms, and mixtures of dosage forms will be addressed below in the section on stability, although mention might be made here of one representative preformulation study that considered the stability of an antiviral compound. Results found using a reversed-phase LC method were compared to spectrophotometric analysis in order to determine reaction kinetics. Drug stability was found to be vehicle-dependent with suspensions in carboxymethylcellulose and methylcellulose being less prone to degradation than others.

An extremely fruitful area of research and publication in the field of preformulation testing by LC is that of partition coefficient or lipophilicity determination. Several standard procedures are available, including the relationship between partition coefficient and reversed-phase retention behavior ( $\log P$  versus  $\log k$ ). Many variations in method and calculations have been proposed, such as comparison with an internal standard partitioning, variation in organic content of the mobile phase for the retention model, and rudimentary assay of organic and aqueous phase in the shake-flask experiment by LC.

A representative publication using these methods is a study in which lipophilicities and solubilities were measured for four 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors by LC. Partition coefficients were determined in this study by LC analysis of drug content in the aqueous phase before and after equilibration with *n*-octanol and were then compared to retention factors in a reversed-phase LC system. The hydroxyacid form of pravastatin was found to have the lowest oil in water partition coefficient ( $P$  o/w) with simvastatin the highest.

## Formulation Development – Stability

In the formulation of prototype dosage forms, clinical supplies and proposed products, many considerations must be met such as sourcing, processing, manufacturing scale, dose requirements, marketing directives, bioavailability, packaging and documentation, besides the formula. These must be met no matter which dosage form is developed – oral solid (tablet, capsule), oral liquid (solution, suspension), ophthalmic, parenteral (solution, suspension), suppository, topical, aerosol, spray, transdermal, or implant. In the development of any dosage form, an overriding question, aside from the above requirements, is product stability along with the necessary drug substance stability. These must be demonstrated at each stage of development with short-term stress testing being useful in formulation prototype

selection and long-term formal stability studies required for submission to regulatory authorities in support of both clinical (IND) testing and proposed product (NDA) marketing. The stability studies on clinical products are conducted with the product contained in packaging not necessarily identical to the desired market package. Final long-term studies for drug product, however, must be conducted in the proposed package for marketing. Accumulated data from these studies in the form of reports are compiled along with formulation, manufacturing instructions, process information, specifications, tests and methods for the drug substance, drug product and excipients, results of batch analysis, certificates of analysis, components description, manufacturer description diagrams, organizational chart, drug master file references, manufacturing batch records, reprocess options, process validation, packaging components description, specifications, tests and sampling procedures, drug substance synthesis, drug reference standard characterization, drug substance preformulation report and other sections as part of the chemistry, manufacturing and control (CMC) submission.

Following IND approval and during clinical tests, drug product used in this testing must also be stability tested over the use period. This involves subjecting product stored in bulk or in its clinical packaging to testing on a schedule with storage at specified temperatures. Results are filed in support of clinical batch manufacturer.

Once a drug product is approved for marketing it is further stability tested with a commitment to test the first three batches for each dosage strength and the first production batch each quarter or year in the concurrent stability testing program. Testing can proceed each three months for the first year, each six months for the second year and at the end of the third year. Results obtained from these production batches stored under specified conditions are entered into annual reports that are submitted to the authorities to support the marketed product.

When reformulation of approved products, new packaging or new sources of drug substance are investigated, stability studies must be conducted as well. Needless to say, all of the above-mentioned stability testing requirements involve assays for potency, whether of drug product or drug substance, and many involve impurities and degradation product determinations as well. LC has been shown to be the technique of choice for most of this testing.

## Drug Substance Stability

Tests demonstrating drug substance stability take several forms, some of which were mentioned above,

but almost all of which utilize LC. Drug substance stability is addressed in preformulation studies on the solid-state bulk drug as well as the drug in various solutions. When the solid is stressed with heat, light, or humidity, assays and degradation product testing will show the extent of the drug resistance to these insults. When the resulting degradation products match retention times and spectra with known authentic related compounds, this serves as evidence for particular reaction pathways. Alternately, fractions containing unknown degradation products can be collected and structurally identified by spectral means. The combined techniques of LC-mass spectrometry (MS) and LC-MS-MS are routinely being applied successfully to this type of study in pharmaceutical firms.

Preformulation studies of a drug in solution give information on the ability of a drug to survive in a parenteral or oral solution product or the need for lyophilization or dry powder fill to avoid instability. The effects of solution pH, ionic strength, metal ions, common ions, oxygen levels, light intensity and wavelength, cosolvents and excipients can also be determined from this type of study. In fact, results from preformulation solution-state stability testing are extremely useful in elucidating possible bioavailability and drug absorption problems in relation to preclinical and clinical testing.

Drug substance stability is also addressed in analytical methods development validation studies that require a demonstration of selectivity as part of specificity testing. These results are included in CMC submissions in support of the analytical methods. In this testing, drug substance is commonly stressed with acid, base, oxidation, air, heat, light and other conditions to give rise to products that can be separated from the parent compound.

A fourth type of drug substance stability testing that is conducted on pharmaceuticals is formal drug substance long-term stability testing. In these procedures the bulk drug is stored in packaging representative of what would be found on a large scale in the production setting, that is, double polyethylene (PE) bags contained in a fiber box or tube. In certain cases, for shipping purposes bulk drug is packaged in double PE bags in plastic or metal containers, each of which should be simulated in the formal stability study. For comparison, drug substance is also stored in glass ampoules or vials, usually under refrigerator conditions, to provide an analytical reference. A formal protocol of required testing is followed, results are accumulated, and reports are written delineating any stability problems encountered.

The conditions of storage for these formal stability studies are enunciated by regulatory authorities, with

international harmonization tending towards the most encompassing set of rules. The 2003 Revision 2 draft of the Guidance for Industry, Q1A Stability Testing of New Drug Substances and Products by the International Conference on Harmonization (ICH) contains guidelines on the conditions of storage for these formal stability studies. Depending on whether the substance is stored at room temperature, in the refrigerator or freezer, a set of temperatures and relative humidities are given. The current revision of the draft document should always be consulted for specific details. Three batches of drug substance of at least pilot-scale size should be tested in this program, also to include stress testing on a single batch, which will show the effect of high temperature, susceptibility to hydrolysis (in solution), pH stability, oxidation, and light stress in formal studies.

Although much research has been conducted on drug substance stability in relation to formulation stability as described below, the area of drug substance stability alone that has probably received most study is that of solution stability. This typical preformulation testing along with the required LC methods development often includes kinetic analysis of the degradation pathway and products. Some examples of this type of work are outlined here. A full validation study on apidrine indicated that the stability of the raw drug and its dosage form are the same. The samples were stress tested by exposure to heat, oxidation, and acidic and basic environments. LC-MS was used in a stability study on cloxacillin in order to identify degradation products.

The stability of drug substances either as dry powder or in solution and in formulations under light stress is also an area of current interest for pharmaceuticals, often using LC to study drug degradation reactions. Benzydamine, for example, was shown to be unstable under UV radiation in gel, cream, or mouthwash preparations.

A related field of research that has found certain applications in pharmaceutical analysis is flash photolysis. This technique has been adapted with UV absorbance, fluorescence, and electrochemical detection of photolysis products separated by LC to enhance limits of detection and quantification. Products of these reactions have also been further investigated following LC separation.

### Drug Product Stability

During bulk drug stability and preformulation testing, preliminary formulations and processes are developed that are first stability tested on a short-term, accelerated basis. Drug product intended for clinical use after IND approval must be stability

tested before IND submission, with preferably 3–6 months' data minimum at submission time. This means that specific analytical methods must be developed during the latter stages of formulation development of the clinical product.

Further formulation changes, selection, and approvals occur during clinical testing with the intent of developing the proposed product for marketing. Each formulation must have new stability-indicating methods developed for assay and related compound measurement. Stability properties of all products developed for commercialization must be studied and reported in NDA (MAA) or supplemental submissions.

The stability of excipients in dosage forms has not been studied extensively in the past by LC methodology. Regulatory authorities, however, are presently tending towards recommendations of more stability specific assays for excipients, which will supplement the required identification testing. Of the few studies reported, one used ion chromatographic methods to measure sodium metabisulfite in parenteral products. The antioxidant was measured following conversion to the sulfite ion in aqueous solution along with its oxidation product (sulfate ion) by conductivity detection.

### Compatibility Testing

The compatibility testing that will be dealt with here is that of liquid products, both oral and parenteral, with single drug substances in solution or suspension and with mixtures of drug substances in solution or suspension. This type of preparation is common in hospital or clinical settings and is also common in formal stability studies on drug products where demonstrations of stability following dilution or storage in plastic containers, infusion sets, etc., are necessary. Compatibility studies between individual bulk excipients and mixtures of bulk excipients and one or more bulk drug substances will not be considered, although several pharmaceutical firms conduct this type of testing with analysis of drug stability in these mixtures by LC.

Among single drug component studies, usual vehicles for dilution are 5% dextrose (D5W), 0.9% sodium chloride (normal saline, NS), aqueous buffers, peritoneal dialysis fluid, nonaqueous solvents, water for injection, phosphate-buffered saline, bacteriostatic water for injection, bacteriostatic sodium chloride, Ringer's injection, and lactated Ringer's. Stability studies can also be carried out on the drug product solution as such or in specific containers or injection devices. Solutions and suspensions can also be prepared extemporaneously and stability tested to show worthiness for oral, ophthalmic, or rectal administration. The following is an example of the first

listed type of research with analysis conducted by stability-indicating LC methods. Pibenzimol-HCl was diluted to  $0.15 \text{ mg ml}^{-1}$  in 5% dextrose, 0.9% NaCl, and lactated Ringer's solution, where stability was found for 24 h each at 25°C. Stability in glass and poly(vinyl chloride) (PVC) containers was compared with the finding of increased loss after 24 h in lactated Ringer's in glass and plastic and in normal saline in PVC bags. Stability testing of injectable solutions prepared without dilution with common large-volume parenterals (LVPs) or other solutions has also been reported.

Compatibility testing has also been conducted on mixtures of solution dosage forms and parenteral drug products. These mixtures have been stability tested in one or more intravenous solvents as listed above. Methods utilized were reported to be stability-indicating by reference or by actual inclusion of data on separation of components from stressed drug substance. One such study concerned the stability of amrinone and digoxin, procainamide-HCl, propranolol-HCl, sodium hydrogencarbonate, potassium chloride, and verapamil-HCl in intravenous admixtures prepared in 0.45% NaCl or 5% dextrose. **Figure 4** shows five chromatograms from this study run by different methods as necessitated for quantification of the separate components.

### Chiral Separations of Pharmaceuticals

Current national and proposed ICH directives on stability testing of drug substances and drug products suggest that enantiomeric purity be controlled in drug manufacture, storage, and shipment for both bulk drug and product for molecular entities with chiral centers. While development of racemic drugs is still permitted, examples are known in which enantiomeric pairs both have the same biological activity, or have different biological activity, or in which one member is active and the opposite isomer is completely inactive. Because of the possibility of interconversion and racemization, stereochemically specific identity tests and assay methods are to be in place for both drug substance and drug product in order to develop data for submission. If a lack of interconversion was once demonstrated under proposed storage conditions, it might not be necessary to collect further data on each batch of drug or product.

The specific chiral LC methods that have been in use over the past decade have involved three general techniques. The first is precolumn derivatization of the enantiomer or mixture with single-enantiomer reagents to yield diastereomers that are

**Figure 4** Chromatograms of (1) amrinone; (2) digoxin; (3) amrinone, Win 55870 (degradation product of amrinone) and propranolol; (4) amrinone, Win 55870 and verapamil; and (5) amrinone, Win 55870 and procainamide by five different methods. am = amrinone, d = digoxin, w = Win 55870, p = propranolol, v = verapamil and pc = procainamide. (Originally published in Riley and Junkin (1991). © 1991 American Society of Pharmacists, Inc. All rights reserved. Reprinted with permission (reference 92144).)

then separated by nonchiral LC. Secondly, constituents have been added to mobile phases to afford separation of enantiomer pairs on nonchiral stationary phases. Finally, chiral stationary phases have been developed commercially and utilized for the separation of diverse types of drug optical isomers. Abundant references can be found on either of these techniques and several high-quality reviews have been written.

Chiral stationary phases that are currently available can be classified into those containing cavities (cellulose derivatives, cyclodextrins, synthetic polymers, crown ethers, and chiral imprinted gels), affinity phases (bovine serum albumin, human serum albumin,  $\alpha$ -glycoprotein, enzymes), multiple hydrogen-bond phases,  $\pi$ -donor and  $\pi$ -acceptor phases, and chiral ligand exchange phases. This classification scheme was used in a review that gave numerous pharmaceutical examples of separation by

each mechanism. Another review included much information on the use of nonchiral stationary phases with mobile phases developed for chiral separations.

## Quality Control

The control of pharmaceutical quality is one of the primary objectives of drug manufacturers. Quality control (QC) has been defined as actions such as testing, monitoring, and inspecting taken to detect and control defects. In contrast, quality assurance has been defined as all actions necessary, including tests for quality of design and conformance, to provide adequate confidence that an item is fit for use. The control of drug substance and drug product quality, as monitored routinely in operational division QC departments, involves developing sets of tests and specifications for raw materials, intermediates of interest and final products, performing the tests on the subject material, compiling the results and submitting them to regulatory authorities on a regular basis. Reasons for rejection of batches and deviations from specification must be well documented and explained.

The use of LC in the quality control of raw materials and finished products (release and stability testing) is primarily in the area of potency assay and impurity testing. It has also been used in dissolution testing, for which several commercially available automatic and robotic systems incorporate LC with dissolution sampling. Very few useful publications exist on QC applications of LC other than several examples that list quality control or quality assurance in their titles as part of a methods development study. One report, however, did summarize all LC methods of use in quality control found in the US Pharmacopeia (USP) XX and its supplements and addenda. This listed the drug or drug product, stationary phase, mobile phase, detector, and uses of each test. These included identification, purity assay, content assay, content uniformity, and dissolution. A summary paper has also been written on dissolution testing with analysis by LC that would find application in QC work. This study discussed advantages of LC over conventional spectrophotometric analysis as well as multicomponent and low-dose product applications.

## Method Validation

Validation of LC methods in the pharmaceutical industry follows prescribed guidelines as published by regulatory authorities and compendia. The FDA

guideline (2001) has mandated that demonstrations of precision of 20% and accuracy of 80–120% of theoretical method specificity, detection limits for degradation products, and structures of those products be submitted in validations of drug substance LC methods. Methods for drug products are to contain this same information along with recovery data from spiked placebos, proof of no placebo interference (stressed and unstressed), precision results (interlaboratory, interday and intercolumn), and demonstrations of degradation product separation. The USP includes recommendations on method precision, accuracy, limits of detection and quantification as well as selectivity. Proof of method robustness (ruggedness) and linearity of detector response with concentration are also suggested. Short validation packages are made available to the authorities in the IND submission, while all requirements must be fulfilled by NDA submission time.

Although several reports have appeared on the validation of LC methods for specific pharmaceuticals, one particularly comprehensive study discussed system suitability, peak purity, system resolution, system selectivity, and stability-indicating properties. The example used in this work was the method developed for pipecuronium bromide. A final comprehensive method validation review has also shown the importance of each facet: specificity, accuracy, precision, sensitivity, and robustness.

## Isotope Separations

### Introduction

The application of isotopes in science, in general, and in analytical chemistry, in particular, is based on two rather contradictory suppositions. Tracer experiments demand the same or very similar behavior of the isotopically modified and unmodified compounds. The study of the effects of isotopes requires the recognition, measurement, and interpretation of minute differences in the chemical and physical properties of compounds that differ only in their isotopic composition (isotopomers). These differences produce a different behavior of the isotopomers in all types of chromatographic processes, and these isotope effects have been demonstrated experimentally.

As early as in 1938, Urey and co-workers published a paper about enrichment of  $^6\text{Li}$  by means of ion-exchange chromatography and since then work in this field has been continuing till date. Gas-solid chromatography has been used for the separation of hydrogen isotopes, noble gases, some other gaseous elements, and simple compounds. Low-molecular-mass volatile compounds labeled mainly with hydrogen isotopes have been separated by gas-liquid chromatography. During the late 1950s and the 1960s, papers were published concerning small but observable isotopic fractionation with liquid chromatography (LC) of isotopically labeled organic compounds. Over the last 20 years, during which high-performance liquid chromatography (HPLC) has become a common analytical technique, many papers have been published dealing with separation of labeled compounds from their unlabeled counterparts. A review of these works, with a possible explanation of the mechanism of the separation process, is presented.

### Isotope Effects

Chromatography can be considered as a process in which the compounds to be separated interact with a stationary phase and a mobile phase. These mutual interactions differ in magnitude even for different isotopes of the same element. The magnitude of the interaction energy for an isotopic pair depends on many parameters that are discussed below.

It is possible to draw the following general conclusions from the experimental data on isotope effects on the physical properties of molecules:

1. The  $\text{C}-^2\text{H}$  bond is shorter than the  $\text{C}-^1\text{H}$  bond (e.g., in ethane the  $\text{C}-^1\text{H}$  bond length is 111.2 pm; in hexadeuterioethane the  $\text{C}-^2\text{H}$  bond length is 110.7 pm) and exhibits higher electron density than the  $^1\text{H}$  bond. The deuterium atom appears to be smaller than the hydrogen atom. There are small, but measurable differences in the dipole moments, e.g.,  $\mu(\text{CH}_3-^2\text{H}) = 3.7 \times 10^{-32} \text{ C m}$ ;  $\mu(^1\text{HCl}) - \mu(^2\text{HCl}) = 1.7 \times 10^{-32} \text{ C m}$ .

2. The  $\text{C}-^2\text{H}$  bond has a polarizability lower than that of the  $\text{C}-^1\text{H}$  bond.

3. The  $\text{C}-^2\text{H}$  stretching vibrational frequency ( $\sim 2200 \text{ cm}^{-1}$ ) is lower than the corresponding  $\text{C}-^1\text{H}$  frequency ( $\sim 3000 \text{ cm}^{-1}$ ).

4. Heavier isotopes have smaller atomic volume; deuterated compounds have smaller molar volumes than the corresponding unlabeled compounds. The molar volume differences between, e.g., deuterated and ordinary benzene are due to a molecular size effect caused by differences in zero point intermolecular motion of the molecules.

5. Deuterium ( $^2\text{H}$ ) is more electropositive than protium ( $^1\text{H}$ ) and thus some isotope effects can be discussed in terms of inductive effects. This has been clearly demonstrated in the measurement of the secondary isotope effect on ionization equilibria of some deuterated carboxylic acids and protonated amines as shown in Table 1.

6. Deuterated compounds are less lipophilic than the corresponding unlabeled compounds.

7. The above-mentioned experimentally proved statements can also be generalized for other isotope pairs.

**Table 1** Isotope effect on dissociation constants<sup>a</sup>

$\text{C}^2\text{H}_3\text{N}^+\text{H}_3$	0.051
$(\text{C}^2\text{H}_3)_2\text{N}^+\text{H}_2$	0.117
$(\text{C}^2\text{H}_3)_3\text{N}^+\text{H}$	0.207

<sup>a</sup>Willi AV (1983) *Isotope Effects in Chemical Reactions* [in German]. Stuttgart: G. Thieme.

<sup>b</sup>Only the isotope-modified compound is specified in the table.

All these experimentally demonstrated phenomena may influence the chromatographic separation processes. Isotope effects on the chromatographic behavior of compounds labeled with isotopes of heavier elements (carbon, nitrogen, oxygen, etc.) are so small that they can only be detected for simple compounds of low relative molecular mass. The following discussion is limited to deuterated and tritiated compounds and only a few examples are given of separation of heavier isotopes.

It should be pointed out that discussion of isotope effects in terms of inductive or other electronic effects is sometimes helpful but represents a gross simplification. A more exact description of the origin of isotope effects uses zero-point energy and vibrational frequencies of molecules in question.

## Separation Processes

Two basic types of the LC separation processes can be distinguished. By adsorption chromatography on 'classic column' or 'straight phase' HPLC, usually 'ordinary' (unlabeled) compounds elute first, i.e., the separation factor is less than unity. ( $\alpha = k_1/k_2 < 1$ ; subscripts 1, 2, and 3 refer to protium, deuterium, and tritium ( $^3\text{H}$ ), respectively;  $k_i$  is a capacity factor). As mentioned above, deuterated or tritiated compounds are more polar and thus are more strongly bound to polar stationary phases.

Partition chromatography and reversed-phase LC usually lead to the opposite result, i.e., a heavier isotopomer is eluted first ( $\alpha > 1$ ). It has been suggested that a major contribution to the isotope effect is a hydrophobic interaction. The fact that the separation factors are higher (see Table 2) when the mobile phase contains more water demonstrates that they are affected by more restricted motion of C-H bonds (in solute), caused by tighter solvation of C-H bonds within the aqueous mobile phase relative to the hydrophobic stationary phase. On the other hand, a less restricted motion of the C-H bonds in the stationary phase would tend to favor protium over deuterium, and this could contribute to the observed isotope effect.

Another important factor is the position of the label in a molecule. Because these effects are essentially primary isotope effects, the best case is when the isotopic atom is pushed out from the rest of the molecule and is well accessible for an interaction. When an atom in question is in the shadow of a bulky group (e.g., *ortho* hydrogen in benzoic acid) or in an inconvenient configuration, neither hydrophobic interactions nor adsorption can take place, or are greatly suppressed and no separation is attained. Other contributions such as differences in solubility,

molar volume, and adsorption on the residual non-derivatized sites on the silica particles seem to be of far less importance for the magnitude of the isotope effect. The above discussion dealt with a direct interaction of an isotopic atom or bond with the stationary and mobile phases (primary isotope effect). However, there also exist chromatographic separations based on secondary isotope effects. In molecules deuterated or tritiated in the position adjacent to an ionizable functional group, the magnitude of the isotope effect is often greatly enhanced. As follows from Table 1  $\alpha$ -deuterated amines are stronger bases than unlabeled amines, and  $\alpha$ -deuterated acids are weaker acids than their protiated counterparts. In an elution system with pH value close to the  $\text{pK}_a$  values of the deuterated/unlabeled amine pair, this isotope-induced base strengthening would alter the ratio of protonated and unprotonated forms, leading to differences in chromatographic mobility. However, at pH much higher or much lower than the  $\text{pK}_a$  value, where both labeled and unlabeled amines are completely protonated or unprotonated, the  $\text{pK}_a$  effect of isotopic substitution on chromatographic separation is greatly suppressed. A similar effect was observed for labeled carboxylic acids.

Ion-exchange chromatography could be regarded as one form of LC because of the similarity of the experimental procedures. The mechanism of the separation process for labeled polar (ionizable) organic compounds can be simply explained in terms of the primary or secondary isotope effect on the ionization constant. For the separation of the isotopic metal ions other mechanisms can be involved.

The isotopic exchange reaction taking place during the separation process can be expressed as

where L and H refer to lighter and heavier isotopes, respectively, and R and S refer to the resin and solution phases, respectively. The equilibrium constant of this isotopic exchange reaction is larger than unity in the case where the heavier isotope is enriched in the solution phase and the lighter one in the resin phase.

The single-stage (elemental) separation coefficient is then defined as

$$\varepsilon = \alpha - 1 = (C_{L,R} \cdot C_{H,S} / C_{L,S} \cdot C_{H,R}) - 1$$

where C is the concentration or activity.

In almost all cases, the experiments yielded values  $\alpha > 1$ . The heavier isotope is enriched in the solution phase and is eluted first. The theory of isotope separation by elution chromatography and the procedure for the calculation of the separation factor from experimental data was elaborated by Glueckauf. For the case of displacement chromatography the theory was developed by Kakihana and Oi.

The main parameters that can influence the separation process are:

1. The mass difference of the isotope pair  $\Delta M$  (or  $\Delta M/M$ ). For the enrichment of magnesium isotopes, the following values were observed:  $\alpha_{24,25} = 1.015$ ;  $\alpha_{24,26} = 1.029$ ;  $\alpha_{25,26} = 1.014$ .
2. Pauling ionic radii of the isotopes in question. The difference of the Pauling radii for  ${}^6\text{Li}$  and  ${}^7\text{Li}$  is 0.04 pm,  ${}^7\text{Li}$  being smaller.
3. The nature and the type of ion exchanger. The classical strongly acidic cation exchanger and strongly basic anion exchanger usually yielded relatively low separation factors. It was found that the separation factor increases as the degree of cross-linking increases. Crown-ethers and azacrown-ethers (cryptands) bound on the Merrifield-type resins were successfully used in the last two decades, the separation factors being at least one order of magnitude higher. Even though the interaction between the cryptand and the cation is not of the pure ionic nature, the exchange ions takes place. The third type of exchanger is the special (hydrated) inorganic oxides, e.g., hydrous manganese(IV) oxide, tin and titanium antimonate, monoclinic antimonite acid, cubic niobic, and tantalate acid.
4. Type of the counterion or complexing agent.
5. Nature, concentration, pH of the eluent. These parameters can influence dramatically not only the magnitude of the separation factor but even the order

of elution. For example, when the zirconium isotopes were eluted by triammonium citrate the heavier  ${}^{96}\text{Zr}$  was eluted first, while in the diammonium citrate system the lighter one ( ${}^{90}\text{Zr}$ ) was enriched in the solution phase and eluted first.

6. Temperature. At lower temperature the separation factors are larger.

## Survey of Separations

### Hydrocarbons and Their Simple Derivatives

Separation of perdeuterated aliphatic and aromatic hydrocarbons has been performed on reversed-phase columns with similar results (Figure 1). A higher content of water in the mobile phase leads to higher separation factors (Table 2).

Chromatography of various isotopomers of benzoic acid shows a moderate effect of number of deuterium atoms on the separation factor; however, an important effect is exerted by the position of the label (Table 3). Isotopomers containing deuterium in the *ortho* positions display lower isotopic separation than isotopomers with deuterium in *meta* or *para* position. The isotope effects associated with the *ortho* positions are minimal, probably because interactions between *ortho* C–H or C– ${}^2\text{H}$  bonds and the stationary phase are minimized by the steric shielding of the carboxyl group.

[9,10,12,13- ${}^3\text{H}$ ]Linoleic acid methyl ester and [9,10,12,13- ${}^3\text{H}$ ]oleic acid methyl ester were chromatographed on silica impregnated with silver nitrate attaining partial separation from the appropriate [1- ${}^{14}\text{C}$ ]methyl esters. The tritium atom bound on the

formations. During the chromatographic purification of such compounds, isotopic fractionation has often been observed. Good, sometimes baseline, separations of tritiated aldosterone, cortisone, oestrone, testosterone, prednisolone, and estradiol from their unlabeled or <sup>14</sup>C-labeled analogs were obtained in reversed-phase LC, with tritiated compounds eluting first. Other techniques such as column partition chromatography and paper chromatography have also been successful.

Vitamin D (cholecalciferol, structure [I]) is hydroxylated in living organisms to 1,25-dihydroxy- or 24,25-dihydroxy-derivatives. A significant chromatographic isotope effect was observed when both derivatives were labeled with tritium in positions 26 and 27, whereas labeling in positions 23 and 24 caused a substantially smaller effect. A similar behavior was found in the chromatography of the corresponding trimethylsilyl ethers (Table 4). As indicated in the table, the heavier isotopomers were eluted first in the reversed phase, and later than lighter isotopomers in the normal phase.

<sup>g</sup> Radial-pak column.

possessing antibiotic and antifungal properties, leads to the corresponding tetrahydroderivatives [II]. The isotope effect in reversed-phase LC mobility was surprisingly large:  $\alpha = k_1/k_2 = 1.0190$  for the deuterated compound and  $\alpha = k_1/k_3 = 1.0233$  for the tritiated compound. A Partisil 5 C<sub>18</sub> column and a mixture of 0.1% phosphoric acid (45%) with CH<sub>3</sub>CN/THF/H<sub>3</sub>PO<sub>4</sub> (90:20:0.1 v/v/v) (55%) as eluent were used. Even though the chromatographic conditions described do not allow resolution of labeled and unlabeled species, such a possibility exists, e.g., when column recycling system is used.

Reversed-phase LC of deuterated chlorophylls [III] obtained from green algae *Rhodospirillum rubrum* and *Rhodospirillum spheroides* grown in media containing 50%, 80%, 90%, and 99.7% <sup>2</sup>H<sub>2</sub>O exhibited baseline separation from isotopically unmodified chlorophyll. As usual, the labeled species were eluted first, and the greater the percentage of deuterium in the compound the faster it moved along the column (Figure 2, Table 5).

## Drugs

(<sup>2</sup>H<sub>10</sub>)Diphenylhydantoin (phenytoin [IV]) and (<sup>2</sup>H<sub>10</sub>)-5H-dibenz[*b,f*]azepine-5-carboxamide (carbamazepine [V]) were separated from their unlabeled parent compounds by reversed-phase chromatography on a C<sub>18</sub> column with H<sub>2</sub>O/CH<sub>3</sub>CN/THF (80:16:4, v/v/v) as the eluent. Baseline separation was attained even when using extracted serum samples. The calculated resolution for both pairs of isotopomers was 1.3 (resolution  $R_s = (t_2 - t_1)/[0.5(w_1 + w_2)]$ ).

[IV]

[V]

[CH<sub>3</sub>-<sup>3</sup>H]Chlorpromazine [VI] and its metabolite [CH<sub>3</sub>-<sup>3</sup>H]-7-hydroxychlorpromazine were separated on a chemically bonded stationary phase (Spherisorb CN) from their unlabeled counterparts. Although the specific activity of tritiated compound was  $\sim 40 \text{ Ci mmol}^{-1}$  indicating  $\sim 1.5$  tritium atom per methyl group, the measured separation factors were rather high (Table 6). The separation factors depend strongly on the pH of mobile phase, so that the isotope effect on the basicity of the dimethylamino group is probably significant. The labeled species was eluted later.

[VI]

An almost complete resolution was attained between unlabeled and di-, tri-, or tetradeuterated drugs active on the central nervous system – 1,2,3,4,10,14b-hexahydro-2-methyl-dibenzo[*c,f*]pyrazino[1,2-*a*]azepine (mianserin [VII]) and 1,3,4,10,14b-hexahydro-2,7-dimethyl-2H-dibenzo[*c,f*]pyrazino[1,2-*a*]oxazepine (Org GC 94 [VIII]). [3,3,4,4-<sup>2</sup>H<sub>4</sub>]Org GC 94 was chromatographed on  $\mu$ -Porasil column and *n*-hexane-2-propanol (90:10, v/v) to which a solution of 4% ethanol and 0.1%

[VII]

[VIII]

2-(*N*-Propyl-*N*-2-thienylethyl)-5-hydroxytetralinamine (N-0437 [IX]), an effective drug against Parkinson's disease and glaucoma, can be separated from its counterparts deuterated and tritiated at the propyl group. The corresponding diastereomeric glucuronides were prepared by enzymatic synthesis and separated in a reversed-phase LC system (Nova-Pak C<sub>18</sub>). The separation factors were pH-dependent and relatively large, considering the remote positions of the labels from the nitrogen atom, e.g.,  $\alpha_2 = 1.033$ ;  $\alpha_3 = 1.037$ .

[IX]

**Table 6** LC separation factors of chlorpromazine versus tritiated chlorpromazine<sup>a</sup>

<sup>b</sup>Spherisorb CN column.

<sup>c</sup>10% 0.05 mol l<sup>-1</sup> sodium acetate buffer in methanol.

The above-mentioned effect of isotope substitution on the basicity of amines was demonstrated by thin-layer chromatography (TLC) of the popular antidepressant imipramine [X]. [<sup>2</sup>H<sub>10</sub>]Imipramine labeled in both methyl groups and in aromatic rings,

and its parent compound were resolved as individual spots on silica plates using different eluents, in which the presence of ammonia was necessary; e.g., benzene/acetone/ $\text{NH}_4\text{OH}$ , 300:60:1;  $R_F$  [ $^1\text{H}$ ] = 0.24;  $R_F$  [ $^2\text{H}$ ] = 0.18. Labeling on the benzene ring exerted no effect on the chromatographic mobility.

Similar TLC behavior has been observed with (R,S)-6-[ $\text{CH}_3\text{-}^2\text{H}$ ]dimethylamino-4,4-diphenylheptane-3-one  $\cdot \text{HCl}$  ( $[\text{H}]$ methadone [XI]) (silica gel Merck; benzene/methanol/ $\text{NH}_4\text{OH}$ ; 85:15:0.65, v/v/v);  $R_F$  [ $^2\text{H}$ ] = 0.58;  $R_F$  [ $^1\text{H}$ ] = 0.79. Reversed-phase LC showed baseline resolution, whereas gas-liquid chromatography afforded no separation.

### Isotopes of Heavier Elements

Liquid chromatographic separations of the isotopes of elements other than hydrogen have been rather rare. A high-efficiency liquid-liquid chromatographic system consisting of porous silica microspheres covered with 25% (w/w) bis(2-ethylhexyl)phosphoric acid in dodecane as the stationary phase and nitric acid as the mobile phase provided a certain enrichment of heavier isotopes of calcium in front of the elution curve. Separation factors calculated by Glueckauf for  $^{42}\text{Ca}$ ,  $^{45}\text{Ca}$ ,  $^{48}\text{Ca}$  versus  $^{40}\text{Ca}$  were 1.0012–1.0029.

Better resolution was obtained when isotopic pairs of  $^{144}\text{Sm}$ – $^{154}\text{Sm}$ ,  $^{140}\text{Ce}$ – $^{142}\text{Ce}$ , and  $^{151}\text{Eu}$ – $^{153}\text{Eu}$  were chromatographed on LiChrosorb 60 with di-2-propyl-ether/THF/65%  $\text{HNO}_3$  (100:20:5, v/v/v). Heavier isotopes were always eluted first, the separation factors being two orders of magnitude higher than in ion-exchange chromatography (1.030–1.085).

There are only a few references in literature about the liquid chromatographic separations of organic compounds labeled with isotopes heavier than hydrogen. For example, Tanaka *et al.* demonstrated the

oxygen isotope effect in the reversed-phase LC separation of  $^{18}\text{O}$  labeled benzoic acid (Figure 3). They demonstrated that successful separation was due to differences in the dissociation constants between the labeled and parent compounds. The isotope effect was pH-dependent and attained a maximal value around pH 5 (Table 7). An equation was derived to

**Figure 3** Separation of benzoic acid (I) isotopomers by recycle chromatography. Column: Cosmosil 5- $\text{C}_{18}$ -P  $\times$  4.15 cm  $\times$  4.6 mm i.d. determine the <sup>18</sup>O isotope effect on the dissociation constants from LC data. This isotope effect was calculated to be  $^{16}K_a/^{18}K_a = 1.020 \pm 0.002$ . A very good, nearly baseline, resolution was attained in a recycle system for the pair benzoic acid–[<sup>18</sup>O<sub>2</sub>]benzoic acid after five cycles, and for the mixture benzoic acid–[<sup>18</sup>O]benzoic acid–[<sup>18</sup>O<sub>2</sub>]benzoic acid after 17 cycles. Similar results were obtained in the chromatography of [<sup>18</sup>O<sub>2</sub>]-4-chlorobenzoic acid and [OH-<sup>18</sup>O]-4-nitrophenol with their unlabeled counterparts.

The same procedure as above was successfully applied to the separation of aniline and [<sup>15</sup>N]aniline on the same column with 0.05 mol l<sup>-1</sup> acetate buffer containing 5% methanol and 0.01% triethylamine as eluent. At pH 4.24, the separation factor was found to be  $\alpha = k_{14}/k_{15} = 1.010$ . The complete separation was accomplished after 20 cycles.

### Ion-Exchange Chromatography

D-Glucose and (1-<sup>2</sup>H)-D-glucose were separated by anion-exchange chromatography on the CarboPac PA1 column. Elution was accomplished with water and required 18–22 min. The baseline separation was achieved using two columns.

There exist large amounts of published experimental works dealing with enrichment of the metal isotopes (from lithium to uranium) by chromatography on cation-exchange resins. Here, we will present some optimistic and interesting examples.

Extensive work has been devoted to the lithium isotopes. The estimated separation factors varied between 0.992 and 1.065. The highest values of the separation factors were achieved by chromatography on the crown ethers bound on the Merrifield resins.

The isotopes of magnesium were chromatographed on the 1-aza-12-crown-4 and bound on the Merrifield peptide resin. The separation factors were  $\alpha(24/25) = 1.015$ ;  $\alpha(24/26) = 1.029$ ;  $\alpha(25/26) = 1.014$ . Similar values were achieved by chromatography on hydrous manganese(IV) oxide:  $\alpha(24/25) = 1.011$ ;  $\alpha(24/26) = 1.021$ ;  $\alpha(25/26) = 1.011$ .

LC of a column packed with the cryptand polymer was used for the separation of zinc isotopes. The enrichment factors were  $\alpha(67/66) = 0.99967$ ;

$\alpha(68/66) = 1.00018$ ;  $\alpha(70/68) = 1.00072$ . Different contributions, i.e., vibrational energy shift, the nuclear mass shift, and field shift caused by the nuclear size and shape of the isotope were also estimated.

An unusual isotope effect of molybdenum in chemical exchange reaction using dicyclohexano-18-crown-6 (batch method) was observed:  $\alpha(94/96) = 1.0086 \pm 0.0007$ . This extremely high value was not ascribed to field shift effect but due to an anomaly of the vibrational levels.

Ion-exchange chromatography of europium has been carried out in a ligand exchange system (LXS) and an electron exchange system (EXS) on highly acidic cation-exchanger AG-MP 50. The observed separation factor for LXS was  $\alpha(153/151) = 1.000015$  at 80°C and  $\alpha(153/151) = 1.000213$  at 60°C for EXS.

### Introduction

The observation and investigation of luminescent phenomena has a long and delightful history and some of the more important milestones are briefly described here. Naturally occurring luminescence, such as fireflies, St Elmo's fire, and shining flesh has fascinated humans since the dawn of time, with an early record appearing in Chinese literature between 1500 and 1000 BC. A millennium or so later, Aristotle (384–322 BC) astutely noted that these emanations were produced without heat. Subsequently, Caius Plinius Secundus (Pliny the Elder, AD 23–79) described, in detail, a number of luminous organisms. Notwithstanding the revolutionary nature of these observations of bioluminescence, made by two such great philosophers, a rigorous scientific approach to the subject was not taken until the mid-sixteenth century. This study culminated in the publication, in 1555, of a book by Conrad Gesner (1516–1565) concerned solely with luminescence. However, Sir

Robert Boyle (1627–1691), son of the Earl of Cork, who came to be known as the father of analytical chemistry, first categorized the essential differences between incandescence and luminescence in 1668. The following year saw the first artificial luminescence, which accompanied Hennig Brandt's discovery and isolation of elemental phosphorus. More than three centuries passed before the emanations from white phosphorus were correctly characterized as chemiluminescence. Cambridge professor and president of the Royal Society, Sir George Gabriel Stokes (1819–1903), was the first to characterize the bichromatic nature of crystal fluospar as a true emission (actually phosphorescence) in 1845. He also coined the term fluorescence as an analogy to opalescence and noted that in the production of fluorescence the absorption of shorter wavelengths resulted in emission at longer wavelengths (Stokes' law). In 1877, Raziszewski was probably the first to observe chemiluminescence from synthetically produced organic compounds during the preparation of lophine (2,4,5-triphenylimidazole) from hydrobenzamide.

The earliest usage of the word luminescence is credited to Eilhardt Wiedemann (1852–1928), who in 1888 used the term to describe the emission of light that was not the result of a rise in temperature ('cold light'). He defined six classes of luminescence by the source of energy that stimulated the emission.

### Introduction

The observation and investigation of luminescent phenomena has a long and delightful history and some of the more important milestones are briefly described here. Naturally occurring luminescence, such as fireflies, St Elmo's fire, and shining flesh has fascinated humans since the dawn of time, with an early record appearing in Chinese literature between 1500 and 1000 BC. A millennium or so later, Aristotle (384–322 BC) astutely noted that these emanations were produced without heat. Subsequently, Caius Plinius Secundus (Pliny the Elder, AD 23–79) described, in detail, a number of luminous organisms. Notwithstanding the revolutionary nature of these observations of bioluminescence, made by two such great philosophers, a rigorous scientific approach to the subject was not taken until the mid-sixteenth century. This study culminated in the publication, in 1555, of a book by Conrad Gesner (1516–1565) concerned solely with luminescence. However, Sir

Robert Boyle (1627–1691), son of the Earl of Cork, who came to be known as the father of analytical chemistry, first categorized the essential differences between incandescence and luminescence in 1668. The following year saw the first artificial luminescence, which accompanied Hennig Brandt's discovery and isolation of elemental phosphorus. More than three centuries passed before the emanations from white phosphorus were correctly characterized as chemiluminescence. Cambridge professor and president of the Royal Society, Sir George Gabriel Stokes (1819–1903), was the first to characterize the bichromatic nature of crystal fluospar as a true emission (actually phosphorescence) in 1845. He also coined the term fluorescence as an analogy to opalescence and noted that in the production of fluorescence the absorption of shorter wavelengths resulted in emission at longer wavelengths (Stokes' law). In 1877, Raziszewski was probably the first to observe chemiluminescence from synthetically produced organic compounds during the preparation of lophine (2,4,5-triphenylimidazole) from hydrobenzamide.

The earliest usage of the word luminescence is credited to Eilhardt Wiedemann (1852–1928), who in 1888 used the term to describe the emission of light that was not the result of a rise in temperature ('cold light'). He defined six classes of luminescence by the source of energy that stimulated the emission.

The present number of classes of luminescent phenomena is somewhere around 20; however, the boundaries between some of these classifications is more than a little blurred. In stark contrast to incandescence, luminescent phenomena are not only cold but are also of relatively low intensity, for example:

- the mysterious St Elmo's Fire and aurora australis (electro- or radioluminescence);
- emission from rubbing or shattering crystals (triboluminescence);
- the ephemeral blue haze from a glass of gin and tonic in the sunlight (fluorescence);
- the enchanting emanations from 'lightening bugs' (fireflies) on a summer evening (chemiluminescence).

Luminescence is generally less intense than incandescence, but it often emanates from extremely small amounts of matter, which has beneficial implications for analytical science. Nevertheless, the utilization of luminescence for analysis is quite a recent innovation. The following commentary describes the fundamental spectroscopic and chemical principles underlying luminescence in relation to its application in analytical science. As other articles will deal with atomic spectroscopy, this discussion will be restricted to analytical molecular luminescence spectroscopy including fluorescence, phosphorescence, and chemiluminescence (bioluminescence being a special case of chemiluminescence).

By monitoring the relative intensity of luminescence as a function of concentration it is possible to quantitatively determine (often at trace levels) a range of inorganic and organic analytes. Contemporary analytical texts reveal that fluorimetric methodology is far more commonplace than either phosphorescence or chemiluminescence. The research literature, however, indicates an increased acceptance of the latter two spectroscopies particularly when combined with either organized media or flow analysis, respectively. Luminescence methodology generally offers superior selectivity, detectability, and linear calibration range compared to that attainable with absorption spectrometry. Unfortunately, there are a relatively limited number of molecules that will exhibit luminescence thus restricting its applicability compared to absorption techniques. Although all forms of luminescence have a common quantum mechanical basis for emission, the route to the excited state defines their respective class. Given that the theory of photoluminescence is better understood than that of the various related phenomena, a basic synopsis of fluorescence and phosphorescence

is presented prior to an introduction to chemically induced luminescence.

## Photoluminescence

### General Principles

Photoluminescence occurs as the result of electronic excitation within a molecule brought about by the absorption of a photon. The question therefore arises, as the vast majority of molecules do not luminescence, what are the quantum mechanisms that give rise to fluorescence and phosphorescence and how does molecular structure aid or inhibit these processes? **Figure 1** is a Jabłoński diagram, named in honor of the Ukrainian born physicist, Professor Alexander Jabłoński (1898–1980), who is considered by many to be the father of fluorescence spectroscopy. These schematic energy level diagrams are useful tools for the understanding of molecular electronic excitation and deexcitation leading to photon emission. The first observation to be made from **Figure 1** is that fluorescence emission (F) results from an electron falling from the lowest vibrational level of an electronically excited state ( $S_1$ ) to any of the vibrational excited levels of the ground state ( $S_0$ ). Phosphorescence emission (P) is a similar process except that the upper electronic state is a triplet ( $T_1$ ). The terms singlet and triplet refer to the relative spins of the electrons in the ground and excited states. When the spins are paired (antiparallel) the upper level is termed a singlet, and when the spins are unpaired (parallel) a triplet state exists. The nomenclature arises from the observed multiplicity in spectra measured under the influence of a magnetic field. It is noteworthy that  $T_1$  states are less energetic than  $S_1$ ; this is a direct consequence of electrons with parallel spins being further apart thus exhibiting less mutual repulsion (spin correlation, Hund's rule). Hence, for a given compound the phosphorescence emission will occur at longer wavelengths than the fluorescence. The photo-induced promotion of an electron from  $S_0$  directly to  $T_1$  has not been shown in **Figure 1** as the simultaneous change of molecular orbital and electronic spin has a very low probability of occurrence. In fact, such transitions are often referred to as 'forbidden' by the spin selection rule.

As most compounds are not luminescent, this implies that there must be more efficient alternative deexcitation mechanisms available to molecules in  $S_1$  or  $T_1$  states to return to  $S_0$  other than ejection of a photon. To understand the nature of the spectroscopic processes shown in **Figure 1**, their relative rates of occurrence and the influences on the various pathways must be considered.

**Figure 1** A Jablonski diagram for a hypothetical luminescent molecule, where A is absorption, F is fluorescence, P is phosphorescence, VR is vibrational relaxation, IC is internal conversion, EC is external conversion, ISC is intersystem crossing,  $v''$  and  $v'$  are vibrational levels associated with each electronic state,  $S_0$  is the electronic ground state,  $S_1$  and  $S_2$  are excited singlet states and  $T_1$  and  $T_2$  are excited triplet states.

At room temperature in solution, we may assume that all molecules will be in the lowest vibrational level ( $v'' = 0$ ) of the ground state ( $S_0$ ), thus absorption will originate solely from  $v'' = 0$ . According to the Franck–Condon principle, the initial step (absorption of a photon) is extremely rapid, requiring only  $10^{-15}$ – $10^{-14}$  s. Immediately after absorption; either of the excited singlets ( $S_1$  or  $S_2$ ) will undergo vibrational relaxation to their lowest vibrational level ( $v' = 0$ ). This process is extremely efficient with all the excess vibrational energy being transferred to the solvent molecules as heat in around  $10^{-13}$ – $10^{-11}$  s. In the case of excitation to  $S_2$ , the process of internal conversion to the upper vibrational levels of  $S_1$  (IC in **Figure 1**) is rapid and effective. Thus luminescence in solution will usually result from the lowest vibrational level of the  $S_1$  excited state. This is not always the case in gas-phase luminescence where collisional relaxation is far less likely. The fluorescence emission lifetime ( $\tau$ ) is of similar magnitude to the mean lifetime of the excited singlet state ( $10^{-10}$ – $10^{-7}$  s), the latter being inversely proportional to the molar absorptivity.

As the probability of finding an excited state molecule at time  $t$  after removal of the excitation source is  $e^{-t/\tau}$ , then the relationship between luminescence intensity and the mean excited state lifetime is:

$$I = I_0 e^{-t/\tau} \quad [1]$$

where  $I$  is the luminescence intensity at time  $t$  and  $I_0$  is the maximum luminescence intensity during excitation. In practical terms the difference in  $\tau$  values for various analytes can provide extra selectivity when using time-resolved luminescence spectroscopy. **Figure 1** also illustrates that the fluorescence emission spectrum is shifted to longer wavelengths compared to that of the absorption (excitation) spectrum. This is the result of vibrational relaxation both after excitation and after fluorescence and is known as Stokes' shift. From the zeroth vibrational level of the lowest excited singlet ( $v' = 0$ ,  $S_1$ ) it is also possible for radiationless deexcitation to convert all the energy to heat in preference to light. This is termed internal conversion, the quantum mechanical basis for which is somewhat vague. The internal conversion from  $S_1$

to  $S_0$  for aliphatic compounds can be rationalized by the overlapping of the upper vibrational levels of  $S_0$  with those of  $S_1$ . In this case relaxation is rapid and efficient and explains why aliphatic molecules rarely luminesce. Internal conversion also occurs between excited electronic states (as shown in **Figure 1**) due to the overlapping vibrational levels of  $S_1$  and  $S_2$ . At the crossover point the potential energies of the two excited states are equal and as the efficiency of vibrational relaxation is far greater than emission of a photon, internal conversion to the zeroth vibrational level of  $S_1$  occurs rather than fluorescence from  $S_2$ . Therefore, fluorescence from anything but the  $S_1$  state is rare; the blue hydrocarbon azulene (isomeric with naphthalene) is the most well-known exception. In large molecules internal conversion may also result in predissociation (bond cleavage), when the electron moves from an excited state to a high-vibrational level of a lower electronic state. In this situation the vibrational energy is sufficient to cause cleavage of bonds in the unstable excited state. Together with internal conversions, electronically excited states can be deactivated by virtue of their interactions with solvent molecules of other concomitant species present. Such pathways are termed external conversions. As a general rule, those environmental parameters that lower the probability of collisional deexcitation (such as lower temperature, increased viscosity, and organized media) tend also to enhance luminescence.

Whilst the probability of the direct population of  $T_1$  from  $S_0$  by absorption is virtually zero, a kinetically efficient pathway exists from the  $S_1$  state in a number of molecules. The mechanism is known as intersystem crossing and it can be considered as a spin-dependent internal conversion. It should be borne in mind that singlet-triplet transitions are approximately a million times less likely to occur than singlet-singlet or triplet-triplet processes and also that radiationless vibrational deexcitation occurs in around  $10^{-13}$  s. As the mechanism of intersystem crossing relies upon vibrational coupling between  $S_1$  and  $T_1$ , the time required for this spin forbidden process can be estimated to be around  $10^{-8}$ – $10^{-7}$  s. This is of the same order as the lifetime of the radiative transition and therefore intersystem crossing competes with fluorescence. The probability of intersystem crossing is enhanced when the energy difference between  $S_1$  and  $T_1$  is small and when the lifetime of  $S_1$  is relatively long. Intersystem crossing is also aided by the presence of heavy atoms (e.g., iodine and bromine) as substituents on either the solute or the solvent molecules. This so-called heavy-atom effect arises from increased spin/orbital interactions and as such spin reversal becomes

more probable. After intersystem crossing, the molecule rapidly undergoes internal conversion ( $10^{-13}$ – $10^{-11}$  s) to the lowest vibrational level of  $T_1$ .

In a similar manner to fluorescence, phosphorescence can only occur with a radiative deexcitation from  $T_1$  to  $S_0$  and two factors limit the likelihood of this event. Firstly, because the energy difference between  $S_0$  and  $T_1$  is smaller than that between  $S_0$  and  $S_1$ , the vibrational coupling between  $S_0$  and  $T_1$  may be enhanced resulting in more efficient internal conversion. Of more consequence, however, is the relatively long intrinsic lifetime of the triplet excited-state ( $10^{-4}$ – $10^2$  s), which provides more than ample opportunity for collisional deactivation. In fact, this mechanism is predominant and explains why phosphorescence is rarely observed at room temperature in simple solutions (2,3-butanedione and tris(2,2'-bipyridyl)ruthenium(II) are examples). The relatively long lifetime of  $T_1$  arises from the spin forbidden nature of the triplet-singlet state transition; as a consequence phosphorescence is often characterized by an afterglow. This is not seen in fluorescence. Clearly, radiationless processes are much more likely to deexcite a triplet state compared to the ejection of a photon, therefore, phosphorescence is most commonly observed from molecules that are either at very low temperatures (often 77 K), in organized media (micelles), or adsorbed onto solid surfaces.

### Structural and Environmental Influences on Photoluminescence

From the preceding section, it is evident that the molecule's structure and its chemical environment determine whether or not it will luminesce, and to what extent. In order to discuss these variables it is useful to introduce quantum yield ( $\phi$ ) or quantum efficiency. For a luminescent process,  $\phi$  represents the ratio of the number of molecules that emit to the total number excited. For highly luminescent substances  $\phi$  will approach unity and for species that do not luminesce appreciably,  $\phi$  will tend toward zero. Thus the luminescence quantum yield for a particular molecule in a specified environment will be related to the relative rate constants of those pathways which can deexcite the lowest excited state ( $S_1$  or  $T_1$ ). The fluorescence quantum yield can therefore be expressed as follows:

$$\phi_f = \frac{k_f}{(k_f + k_i + k_r)} \quad [2]$$

in which  $k$  represents the various rate constants as designated by the subscripts, where f is fluorescence, i is intersystem crossing, and r is radiationless energy loss, which includes internal and external

conversions plus predissociation or dissociation. Thus, if  $k_f \gg (k_i + k_r)$  then  $\phi_f \rightarrow 1$  and if  $k_f \ll (k_i + k_r)$  then  $\phi_f \rightarrow 0$ . The phosphorescence quantum yield ( $\phi_p$ ) is dependent upon competition between the radiationless routes from  $T_1$  to  $S_0$  and phosphorescence emission. But  $\phi_p$  also relies upon the rate of intersystem crossing which competes with both fluorescence and radiationless deactivation from  $S_1$  and  $S_0$ . Thus  $\phi_p$  is given by:

$$\phi_p = \frac{k_p}{k_p + k'_r} \times \frac{k_i}{k_f + k_i + k_r} \quad [3]$$

where  $k'_r$  represents the combined rate constant for all radiationless pathways from  $T_1$  to  $S_0$ . In the majority of situations  $k_f$  and  $k_p$  are related to molecular structure with only minor dependence upon environmental variables. The magnitude of  $k_i$  can be affected by both these parameters. Both  $k_f$  and  $k'_r$  have only slight dependence upon molecular structure but are markedly affected by the molecular environment.

Photoluminescence resulting from absorption of wavelengths below 200 nm is not common since the subsequent transitions from interaction with such energetic photons are likely to result in deactivation of the excited states via predissociation or dissociation. It is therefore not surprising that luminescence due to  $\sigma^* \rightarrow \sigma$  transitions are virtually nonexistent, in fact most fluorescent or phosphorescent emissions from organic molecules arise from  $\pi^* \rightarrow \pi$  and sometimes  $\pi^* \rightarrow n$  transitions depending upon which is less energetic. Fluorescence is more commonly observed from compounds where the  $S_1 \rightarrow S_0$  transition corresponds to a  $\pi^* \rightarrow \pi$  emission rather than  $\pi^* \rightarrow n$ , which implies that the quantum efficiency resulting from  $\pi, \pi^*$  states is far greater than that from  $n, \pi^*$  states. This situation can be explained by consideration of some spectroscopic parameters for each state (see Table 1).

Because the lower molar absorptivity of the  $n \rightarrow \pi^*$  transitions translates to lower values of  $k_f$ , the relative importance (efficiency) of intersystem crossing is in turn enhanced. The smaller energy differences between  $S_1$  and  $T_1$  for  $n, \pi^*$  states also increases the rate of intersystem crossing. Therefore, if  $S_1$  is an

$n, \pi^*$  state,  $k_i$  in eqn [2] becomes large with respect to  $k_f$  and as such  $\phi_f$  tends toward zero. On the other hand, when  $S_1$  is a  $\pi, \pi^*$  state, lifetimes are much shorter ( $k_i < k_f$ ). There is also less vibrational level overlap between  $S_1$  and  $T_1$  and consequently fluorescence becomes more probable. In general, molecules with low lying  $n, \pi^*$  states do not fluoresce but may phosphoresce given a suitable environment. In such a case emission would result from a  $\pi^*$  to  $n$  transition, but phosphorescence is also observed from  $\pi^*$  to  $\pi$  transitions.

Analytically usable fluorescence is most often observed from compounds with aromatic functionality. Relatively few nonaromatic molecules exhibit fluorescence and those that do often contain carbonyl groups or are highly conjugated. Consistent with the previous discussion, all these species possess low energy  $\pi$  to  $\pi^*$  ( $S_0$  to  $S_1$ ) transitions. The majority of unsubstituted aromatic hydrocarbons exhibit fluorescence in liquid solution and sometimes phosphorescence under specific conditions. Increasing the number of fused rings generally results in emission at longer wavelengths; thus benzene and naphthalene fluoresce in the UV whereas anthracene and naphthacene exhibit blue and green fluorescence, respectively. Substitution on to the aromatic rings causes shifts in the absorption wavelengths, which in turn changes the emission spectra. More importantly, substitution of particular species can drastically affect the quantum efficiency. For example, large (heavy) atoms increase the probability of intersystem crossing to the triplet state and carboxylic acids or carbonyl groups reduce the fluorescence quantum yield since these moieties often possess low level  $n, \pi^*$  transitions. Along with substitution, molecular geometry also affects luminescence. This can be illustrated by considering two structurally similar compounds: fluorescein(1), which is intensely fluorescent; and phenolphthalein(2), which is not fluorescent. The only difference between the two structures is the oxygen bridge present in fluorescein, which imparts rigidity to the molecule. In phenolphthalein electronic excitation can be lost internally via vibration and rotation rather than photon emission. In structurally rigid molecules, energy dissipation via vibration and internal rotation is far less efficient. Enhanced phosphorescence can result from adsorption of the emitting species on to a solid surface to provide added rigidity. Such molecular inflexibility is often used to rationalize the observed increase in fluorescence intensity of organic complexing agents when chelated to a metal cation. Thus, the complexes of  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Zn}^{2+}$ , and  $\text{Al}^{3+}$  with 8-quinolinol-5-sulfonic acid are much more fluorescent than the free ligand molecule itself.

**Table 1** A comparison of  $n, \pi^*$  and  $\pi, \pi^*$  singlet states

	$n, \pi^*$	$\pi, \pi^*$
Molar absorptivity ( $1 \text{ mol}^{-1} \text{ cm}^{-1}$ )	$10\text{--}10^3$	$10^3\text{--}10^5$
Lifetime(s)	$10^{-7}\text{--}10^{-5}$	$10^{-10}\text{--}10^{-7}$
Energy difference between $S_1$ and $T_1$	Small	Often large
Rate constant for intersystem crossing ( $k_i$ )	$> k_f$	$< k_f$

It is worth mentioning that while many metal ions form rigid complexes with 8-quinolinol-5-sulfonic acid, relatively few exhibit analytically useful fluorescence. This is due to the internal heavy atom effect and/or paramagnetism causing intersystem crossing, which is manifested (in some instances) by increased intensity of phosphorescence.

Together with molecular structure, environmental parameters such as temperature, solvent type, viscosity, pH, and dissolved oxygen content can also affect luminescence. As the solution temperature rises, it follows that the number of collisions between the excited state molecule and the solvent molecules will increase, thus greatly improving the likelihood of radiationless deexcitation to the ground state. Therefore,  $\phi_f$  for most compounds decreases with increasing temperature. As mentioned earlier, the effect of temperature upon  $\phi_p$  is even more dramatic due to the vastly greater lifetime of triplet states.

By similar reasoning an increase in viscosity (via organized media) will serve to limit collisional energy transfer and thus enhance luminescence. The heavy atom effect discussed earlier in relation to molecular structure can be used to explain the depression of fluorescence with solvents or solutes containing such species. Carbon tetrabromide and ethyl iodide can be used to limit fluorescence by promoting intersystem crossing with a resultant enhancement of phosphorescence. The absorption of a photon causes a change in electronic distribution and, therefore, molecular geometry. This can often lead to a considerable difference in polarity between the ground and excited states. If the excited state has increased polarity then in polar solvents luminescence will be shifted to longer wavelengths compared to that observed in a nonpolar medium. This results from the increased stabilization of the excited state relative to the ground state. Solvent polarity can also affect the type of luminescent phenomena observed. For example, in cyclohexane, isoquinoline exhibits intense phosphorescence (at 77 K), yet the same compound in either water or ethanol gives only fluorescence. In protic solvents the lone pair on the nitrogen ( $n$ -orbital) is solvated which lowers its energy relative to the  $\pi^*$  orbital; as a consequence the  $\pi, \pi^*$  becomes the lowest lying state and, as discussed earlier, fluorescence is preferred. The reverse is the case in

cyclohexane, with the low lying  $n, \pi^*$  being prone to intersystem crossing and then phosphorescence.

The control of pH in a solution containing a luminescent analyte is also of great importance for sensitive and reliable analysis. For aromatic compounds with acidic or basic substituents, excitation and emission wavelengths of the ionized and free forms are likely to differ. In the case of fluorescence from metal chelates, the pH must be controlled to ensure that the conditional stability constant for the complex is optimal for the particular analytical situation.

Dissolved molecular oxygen can quench both fluorescence and phosphorescence albeit with different efficiencies and mechanisms. The extent of oxygen quenching on fluorescence is strongly dependent on the fluorophore, whereas for phosphorescence the intensity is always adversely affected. This can be rationalized using the Stern–Volmer equation [4] assuming no other quenching species are present.

$$\frac{\phi_Q}{\phi_0} = \frac{1}{(1 + k_Q \tau [Q])} \quad [4]$$

where  $\phi_Q$  and  $\phi_0$  are the luminescence quantum yields in the presence and absence of the quencher, respectively,  $[Q]$  is the molar concentration of the quenching species and  $k_Q$  is the rate constant for the quenching interaction. Given that quenching is diffusion limited ( $k_Q \approx 10^{10} \text{ mol}^{-1} \text{ s}^{-1}$ ) and that the concentration of oxygen in water at atmospheric pressure is  $\sim 10^{-3} \text{ mol l}^{-1}$  then eqn [4] becomes:

$$\frac{\phi_Q}{\phi_0} = \frac{1}{(1 + 10^7 \tau)} \quad [5]$$

Since phosphorescence lifetimes in the absence of oxygen are in the range  $10^{-4}$ – $10^2 \text{ s}$ , the ratio of the quantum yields (from eqn [5]) will be extremely small for most phosphorescent species. However, as fluorescent lifetimes in the absence of oxygen vary from  $10^{-10}$  to  $10^{-7} \text{ s}$ , the diffusion controlled oxygen quenching of singlet states will be most efficient for the longer-lived species. Numerous mechanisms have been proposed for the quenching of fluorescence by molecular oxygen. The most likely pathway involves enhancement of intersystem crossing by the triplet oxygen, which can be summarized as follows:

The mechanism of intersystem crossing ( $^1X^*$  to  $^3X^*$ ) is thought to occur via a transient charge-transfer species between the excited fluorophore ( $X^*$ ) and molecular oxygen. Although molecular oxygen promotes intersystem crossing, it does not enhance

phosphorescence. As discussed earlier, the long lifetime of the radiative transition precludes phosphorescence being observed in simple solution due to quenching by collisional deactivation. The mechanism for the quenching of triplet states in solution by molecular oxygen (or other triplets) is at best speculative, possibly involving triplet–triplet annihilation. The ability of molecular oxygen to efficiently quench photoluminescence can, however, be exploited for the sensitive determination of oxygen in liquids and solids.

Paramagnetic transition metal ions may also quench solution luminescence by increasing the rate of intersystem crossing. However, there are numerous exceptions to this simple mechanism including manganese(II) ions, which are generally poor quenchers of luminescence but are highly paramagnetic. Diamagnetic main group metal ions are usually inefficient quenching agents. It is therefore clear that other processes may be involved in the interaction of metal ions with luminescent species. Excited state complex formation and energy transfer are both likely in some instances. From a practical analytical point of view, the quenching of luminescence by any concomitant species in real samples must be investigated during method development and either removed or compensated for.

### The Relationship between Photoluminescence Intensity and Analyte Concentration

The relationship between emission intensity and analyte concentration can be derived using the Lambert–Beer law in conjunction with the schematic of a spectroluminometer in Figure 2.

If the incident radiation ( $\lambda_{\text{ex}}$ ) has the power  $P_0$  and a portion of this is absorbed over  $b_1$  then the radiant power striking the central region of the sample ( $P'_0$ ) is given by:

$$P'_0 = P_0 10^{-\epsilon_{\text{ex}} b_1 C} \quad [6]$$

where  $\epsilon_{\text{ex}}$  is the molar absorptivity at  $\lambda_{\text{ex}}$ . It follows that the radiant power of the exciting beam after traversing  $b_2$  ( $P'$ ) is:

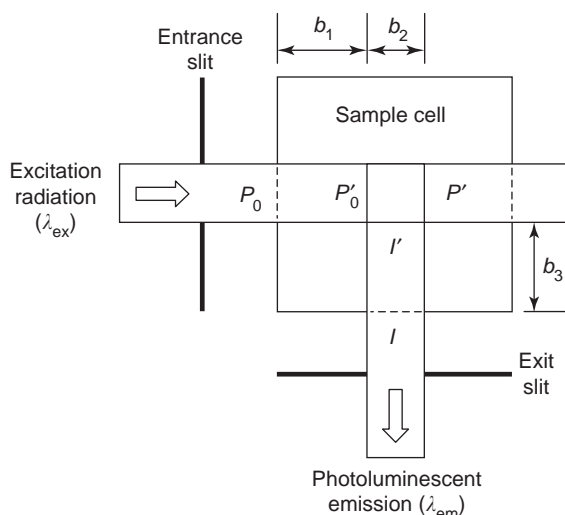

$$P' = P'_0 10^{-\epsilon_{\text{ex}} b_2 C} \quad [7]$$

The luminescence intensity ( $I'$ ) is proportional to both the amount of light absorbed and the quantum efficiency ( $\phi$ ) such that:

$$I' = \phi(P'_0 - P') \quad [8]$$

A fraction of the emitted radiation will be absorbed over the pathlength  $b_3$  and this can be expressed in terms of the observed luminescence intensity ( $I$ ):

$$I = I' 10^{-\epsilon_{\text{em}} b_3 C} \quad [9]$$

**Figure 2** A schematic representation of the sample compartment of a photoluminescent spectrometer.

where  $\epsilon_{\text{em}}$  is the molar absorptivity at  $\lambda_{\text{em}}$ . By rearranging eqns [6]–[9] the following relationship between  $P_0$  and  $I$  can be obtained:

$$I = \phi P_0 10^{-\epsilon_{\text{ex}} b_1 C} (1 - 10^{-\epsilon_{\text{ex}} b_2 C}) 10^{-\epsilon_{\text{em}} b_3 C} \quad [10]$$

At low analyte concentrations  $I$  is proportional to  $C$  as absorption is small. Since the absorbance increases faster than emission at high analyte concentrations the resultant  $I$  value reaches a maximum and then decreases as seen in Figure 3. This is termed self-absorption and it occurs when  $\lambda_{\text{em}}$  overlaps the absorption band. Self-quenching also decreases the luminescence intensity at high concentrations as it results from a radiationless energy transfer between two excited molecules and the solvent in a similar fashion to external conversion. Under certain conditions self-absorption and self-quenching may result in a maximum in the calibration function. Equation [10] can be simplified at low analyte concentrations; absorbance will be negligible and the three exponents will become very small. Therefore, we can replace the terms  $10^{-\epsilon_{\text{ex}} b_1 C}$  and  $10^{-\epsilon_{\text{em}} b_3 C}$  by unity. Clearly, the term  $10^{-\epsilon_{\text{ex}} b_2 C}$  cannot be treated in this way or eqn [10] would become zero:

$$I = \phi P_0 (1 - 10^{-\epsilon_{\text{ex}} b_2 C}) \quad [11]$$

The term in eqn [11] can subsequently be expanded as a MacLaurin series to give:

$$I = \phi P_0 \left[ \epsilon_{\text{ex}} b_2 C \ln 10 - \frac{(\epsilon_{\text{ex}} b_2 C \ln 10)^2}{2!} + \frac{(\epsilon_{\text{ex}} b_2 C \ln 10)^3}{3!} \dots + \frac{(\epsilon_{\text{ex}} b_2 C \ln 10)^n}{n!} \right] \quad [12]$$

When the solution absorbance is small ( $\epsilon_{\text{ex}} b_2 C < 0.05$ ) it is a good approximation to neglect all

**Figure 3** Photoluminescence calibration for an aqueous solution of tris(2,2'-bipyridyl)ruthenium(II) chloride hexahydrate,  $\lambda_{\text{ex}} = 457 \text{ nm}$ ,  $\lambda_{\text{em}} = 609 \text{ nm}$ .

but the first term in the series:

$$I = \phi P_0 \epsilon_{\text{ex}} b_2 C \ln 10 \quad [13]$$

Therefore, when the absorbance is small (at constant  $P_0$  and under a defined chemical environment) the observed emission intensity is directly proportional to analyte concentration:

$$I = KC \quad [14]$$

In most analytical applications the above conditions are met; and although the linear dependence of  $I$  upon  $P_0$  is not infinite, it provides a significant advantage for photoluminescence over absorption spectrophotometry.

### Excitation and Emission Spectra

**Figure 4** shows both the emission (A) and excitation (B) spectra of anthracene in ethanol ( $c. 1 \mu\text{g ml}^{-1}$ ). The former was recorded with a fixed excitation wavelength of 340 nm and the latter was monitored at an emission wavelength set to 379 nm. The four peaks in **Figure 4A** are transitions from the zeroth vibrational level of  $S_1$  to the excited vibrational levels of  $S_0$ . Conversely, the four peaks in **Figure 4B** correspond to transitions between the zeroth vibrational level of  $S_0$  and the various vibrational levels of  $S_1$ . The approximate 'mirror image' appearance of the two spectra occurs due to the similarities in the energies of the vibrational levels in  $S_0$  and  $S_1$ .

The difference in wavelength between the excitation and emission spectra is a characteristic of photoluminescent molecules and is known as the Stokes' shift, which can be quantified into wavenumbers by

**Figure 4** Fluorescence spectra of anthracene ( $1 \mu\text{g ml}^{-1}$ ) in ethanol. The emission spectrum (A) was obtained with  $\lambda_{\text{ex}} = 340 \text{ nm}$  and the excitation spectrum (B) was obtained with  $\lambda_{\text{em}} = 379 \text{ nm}$ .

the following relationship:

$$\text{Stokes' shift} = 10^7 \left( \frac{1}{\lambda_{\text{ex}}} - \frac{1}{\lambda_{\text{em}}} \right) \quad [15]$$

where  $\lambda_{\text{ex}}$  and  $\lambda_{\text{em}}$  are the corrected wavelengths of the maximum excitation and emission, respectively (in nanometers). In order to record corrected excitation and emission spectra the wavelength dependence of the source, monochromators, and photomultiplier response must be identified and accounted for. The presence of the extraneous peak in the emission spectrum can be attributed to Rayleigh scattering of the excitation radiation. This is most commonly observed at either the excitation wavelength or twice this value due to second order diffraction from the grating in the emission spectrometer. Anthracene also exhibits phosphorescence in ethanol at 77 K with the wavelength of maximum emission being 462 nm. This is consistent with the lower energy of the lowest excited triplet state.

### Chemiluminescence

All chemical reactions are accompanied by energy changes. Any excess energy is usually dissipated by collision in around  $10^{-12} \text{ s}$ . Chemiluminescence is commonly observed at wavelengths from the near ultraviolet to the near infrared (which correspond to

excess chemical energy in the range from 340 to 130 kJ mol<sup>-1</sup>, respectively). Whilst these amounts of excess energy are achievable with certain reactions (often redox), the generation of chemiluminescence depends upon the suitable molecular structure of intermediates or products that will facilitate the conversion of chemical potential to electronic excitation.

After chemical generation of the excited state has occurred, all of the environmental factors that influence photoluminescence are equally valid for chemiluminescence. It is generally accepted that most chemiluminescence reactions can be thought of as chemically induced fluorescence based upon the rarity of phosphorescence occurring in simple solution. Two noteworthy exceptions are the reduction of (1) tris(2,2'-bipyridyl)ruthenium(III) and (2) acidic potassium permanganate in the presence of certain polyphosphates. The emission in these cases appears to originate from very short-lived triplets. Many chemiluminescent reactions can produce light for several minutes or even longer. It should be emphasized that this is indicative only of the reaction kinetics, which produce the emitting species, and not the lifetime of the excited state.

Chemiluminescence can be rather simply classified as either direct or indirect. The former can be thought of as follows:

where A and B are reactants employed to produce either a product or intermediate in an electronically excited state (C\*) that returns to its ground state by ejection of a photon ( $h\nu$ ).

Indirect chemiluminescence has been used extensively for analysis and in the so-called chemical light sources; the most well known of these reactions involve oxidation of certain diaryl oxalates and oxamides. Instead of C\* returning to the ground state by photon ejection (as in the above reaction scheme), it can undergo energy transfer with a suitable fluorophore, which in turn may then exhibit its characteristic fluorescence emission:

The analytical utility of indirect chemiluminescence depends upon little or no emission resulting from C\* in the region of maximum emission from the electronically excited fluorophore together with efficient transfer of excitation energy.

## Bioluminescence

The emission of light from fireflies has enchanted observers for millennia. However, it was not until comparatively recently (1947) that adenosine triphosphate (ATP) was identified as being the key component in the enzymatically controlled luciferin luminescence. The analytical utility of firefly bioluminescence was first demonstrated in 1952. Since that time the luciferin–luciferase reaction has been extensively employed for analysis in a wide variety of scientific disciplines.

While there are numerous species of firefly having similar biochemical pathways for the generation of light, the proposed mechanism for the luciferin–luciferase reaction is based upon the system of *Photinus pyralis*. The oxidation of D-luciferin (3) by oxygen, which is catalyzed by the enzyme luciferase, is thought to proceed by the sequence outlined below:

where E is the enzyme luciferase, L is luciferin (3), AMP is adenosine monophosphate, PP is pyrophosphate and L = O is oxyluciferin (4).

In the initial step, the D-luciferin is activated via interaction with Mg-ATP to give the enzyme bound D-luciferyl adenylate and pyrophosphate. As shown, this reaction is reversible and therefore pyrophosphate can impede the forward reaction. Generally, only low levels of pyrophosphate are formed from the concentrations of ATP and luciferase present under normal reaction conditions. The second step is an oxidative decarboxylation which produces oxyluciferin (4) in an electronically excited state. The excited oxyluciferin returns to the ground state by the ejection of a photon ( $\lambda_{\text{em}} = 562 \text{ nm}$ ) with an impressive overall quantum yield of  $\sim 0.9$  (at 25°C and pH 7.8). The light intensity is directly proportional to the ATP concentration provided that the level of luciferin remains constant.

There are numerous other bioluminescent systems of analytical importance, which have been isolated from various natural sources. A more detailed

## Other Types of Luminescence

Other classes of luminescence have been used in analytical applications; some examples are provided in Table 2. Thermally stimulated luminescence (or thermoluminescence) is the emission arising during mild heating of a solid material, often after it has been subjected to ionizing radiation. Thermoluminescence has been extensively employed for dating and dosimetry, including (for example) the detection of irradiated foods. Some incandescent solids emit at much shorter wavelengths than expected due to ‘candoluminescence’, which has been exploited for the detection of metals such as manganese, antimony, cerium, europium, terbium, lead, and bismuth.

Radioluminescence – induced by gamma- or X-rays – has also been exploited for dating. Radioluminescent light sources have been designed for spectrometric studies; the radioisotope and scintillation medium allows independent selection of the spectral and temporal characteristics. Sonoluminescence, the emission observed when particular solutions are exposed to ultrasonic waves, has the potential for analytical applications involving the detection of medium-to-high concentrations (over  $10\text{ g dm}^{-3}$ ) of elements that have an ionization energy below 7.65 eV and a boiling point below  $2700^{\circ}\text{C}$ .

Triboluminescence (arising from solids during structural rearrangements such as crushing) has limited applicability in analytical chemistry, but has been examined as a tool for clinical diagnosis with blood samples. The use of triboluminescent materials to detect damage in composite structures during impact has been suggested.

### Introduction

Luminescence – fluorescence, phosphorescence, and even chemiluminescence – may be emitted from the surface of powdered solid supports with small-sized particles or from membranes coming from compounds immobilized by physical or chemical procedures when exposed to by external radiation. The selectivity, sensitivity, speed, flexibility, and simplicity of solid-phase luminescence spectrometry (SPLS) make it a good analytical tool, especially in trace analysis. Because of its ease in handling, the use of SPLS has increased in different fields of interest and many different formats have emerged.

The reasons for the increase in the use of SPLS lie in its multidimensional character (spectral, lifetime, polarization, and other measurements) as well as in the need for a system that shows a large number of reactions and processes very efficiently. The advantages of SPLS include its sensitivity, low cost, ease in performance, versatility, and that it offers subnanometer spatial resolution with submicrometer visualization and submillisecond temporal resolution.

The reasons for the widespread use of SPLS luminescence are varied and generally make use of: improvements in the photophysical emission process, convenience of use, possibility of preconcentration, and use of a solid phase as a carrier for reactions or as a matrix for depositing or protecting reagents.

Referring here only to analytical purposes, SPLS is used for detection or determination of intrinsically fluorescent or phosphorescent compounds, for non-luminescent compounds that are capable of showing luminescence when they are derivatized, for non-luminescent, nonderivatized compounds that are capable of modifying the luminescent properties of a probe, i.e., via quenching or solvatochromic effect, and for compounds that interact via a binding partner and indicate this reaction with a luminescent label.

The different ways in which luminescence in solid phases is measured are: as a simple support, i.e., in intrinsically fluorescent compounds; as a support that makes a luminescent process possible in certain chemical conditions, i.e., phosphorescence; as a phase for preconcentrating the analyte or a derivative from a diluted solution due to the favorable distribution constant, i.e., polycyclic aromatic hydrocarbons (PAHs) on paper or C<sub>18</sub>-silica; as a phase that contains one or more immobilized reagents in a monolayer or multilayer format, enabling the reaction and retention of the analyte as well as different processes such as separation or others, i.e., test strips; as a phase that contains a compound that modifies its luminescent characteristics upon contact with the analyte, i.e., oxygen acting on a metallophorphyrin embedded in a polymer.

### Principles

Fluorescence arises from transitions that occur between singlet states and is not significantly modified upon being emitted from a solid substrate with respect to the solution, although in general the quantum yield is higher than in solution, while in the case of phosphorescence there are striking differences in quantum yield between solid and solution. Phosphorescence generally involves an intersystem crossing to a triplet state, and a subsequent radiative transition that is rather slow. In this case, nonradiative relaxation is the usual deactivation process of the long lifetime excited triplet state, due to intermolecular collisional quenching processes and intramolecular vibrational–rotational relaxation. Fixing a potentially phosphorescent analyte on a solid phase hinders its motion in this rigid environment and restricts radiationless deactivation, protecting the triplet state and increasing the quantum yield. There are two main solid-phase immobilization techniques: physical trapping in the rigid glass formed at low temperature and retention on a solid phase at room temperature. We are concerned with this second technique.

While in solution luminescence components are dissolved, in SPLS the electromagnetic radiation that

### Introduction

Luminescence – fluorescence, phosphorescence, and even chemiluminescence – may be emitted from the surface of powdered solid supports with small-sized particles or from membranes coming from compounds immobilized by physical or chemical procedures when exposed to by external radiation. The selectivity, sensitivity, speed, flexibility, and simplicity of solid-phase luminescence spectrometry (SPLS) make it a good analytical tool, especially in trace analysis. Because of its ease in handling, the use of SPLS has increased in different fields of interest and many different formats have emerged.

The reasons for the increase in the use of SPLS lie in its multidimensional character (spectral, lifetime, polarization, and other measurements) as well as in the need for a system that shows a large number of reactions and processes very efficiently. The advantages of SPLS include its sensitivity, low cost, ease in performance, versatility, and that it offers subnanometer spatial resolution with submicrometer visualization and submillisecond temporal resolution.

The reasons for the widespread use of SPLS luminescence are varied and generally make use of: improvements in the photophysical emission process, convenience of use, possibility of preconcentration, and use of a solid phase as a carrier for reactions or as a matrix for depositing or protecting reagents.

Referring here only to analytical purposes, SPLS is used for detection or determination of intrinsically fluorescent or phosphorescent compounds, for non-luminescent compounds that are capable of showing luminescence when they are derivatized, for non-luminescent, nonderivatized compounds that are capable of modifying the luminescent properties of a probe, i.e., via quenching or solvatochromic effect, and for compounds that interact via a binding partner and indicate this reaction with a luminescent label.

The different ways in which luminescence in solid phases is measured are: as a simple support, i.e., in intrinsically fluorescent compounds; as a support that makes a luminescent process possible in certain chemical conditions, i.e., phosphorescence; as a phase for preconcentrating the analyte or a derivative from a diluted solution due to the favorable distribution constant, i.e., polycyclic aromatic hydrocarbons (PAHs) on paper or C<sub>18</sub>-silica; as a phase that contains one or more immobilized reagents in a monolayer or multilayer format, enabling the reaction and retention of the analyte as well as different processes such as separation or others, i.e., test strips; as a phase that contains a compound that modifies its luminescent characteristics upon contact with the analyte, i.e., oxygen acting on a metallophorphyrin embedded in a polymer.

### Principles

Fluorescence arises from transitions that occur between singlet states and is not significantly modified upon being emitted from a solid substrate with respect to the solution, although in general the quantum yield is higher than in solution, while in the case of phosphorescence there are striking differences in quantum yield between solid and solution. Phosphorescence generally involves an intersystem crossing to a triplet state, and a subsequent radiative transition that is rather slow. In this case, nonradiative relaxation is the usual deactivation process of the long lifetime excited triplet state, due to intermolecular collisional quenching processes and intramolecular vibrational–rotational relaxation. Fixing a potentially phosphorescent analyte on a solid phase hinders its motion in this rigid environment and restricts radiationless deactivation, protecting the triplet state and increasing the quantum yield. There are two main solid-phase immobilization techniques: physical trapping in the rigid glass formed at low temperature and retention on a solid phase at room temperature. We are concerned with this second technique.

While in solution luminescence components are dissolved, in SPLS the electromagnetic radiation that

impinges on the solid matrix and the luminescence radiation that is given off is scattered. Usually, a fraction of the analyte penetrates the solid phase to depths that differ depending on the solid phase, and luminescence is excited on the surface and within the matrix, giving off diffuse luminescence due to multiple scattering by particles or fibers of the solid phase. Diffusively transmitted luminescence may appear on the unexcited side of the support; however, it is the diffusively reflected luminescence that is usually measured.

Two different strategies have been employed to put the analyte in contact with the solid phase. The first consists of the use of membranes on which the analyte or a derivative is retained and which contain some or none of the necessary reagents. When placed in contact with the sample via immersion, moistening, or depositing a volume of the sample or an extract of it, either the analyte or a derivative of it is retained on the solid phase or interacts with some reagent present in it, generating the luminescent response that is then measured on the membrane itself. The second approach uses powdered solid supports with small-sized particles that are placed in contact with the sample, usually in a solution. The collection of this solid and the direct measurement of a luminescent property make it possible to then quantify the analyte.

The two methods – membranes and powdered supports – share the same basic concept and both are capable of being automated, though in different forms. In the first case, the solid supports are packed into flow-through cells and use flow-injection analysis (FIA) type systems. Membranes, on the other hand, have been implemented in probe-type systems both in batch or continuous mode.

## Types of Solid-Phase Procedures and Applications

### Batch Procedures

Batch mode can be performed in membranes and in powdered solids. The simplest procedures use the solid phase as a medium to support the analytes and carry out the measurement. Among membranes, a variety of cellulosic supports have been used, and the nature of the analyte plays an important role in producing luminescence. Polar or ionic molecules give off a strong adsorption interaction due to hydrogen bonding and induce intense phosphorescent signals, while nonpolar compounds produce weak dispersion interactions and small shifts in fluorescence spectra and weak phosphorescence. External heavy-atom perturbation can be used to induce

intense phosphorescence. Other membranes include filter paper treated with different chemicals such as NaF,  $\text{NH}_4\text{Cl}$ ,  $\text{NaCH}_3\text{COO}$ , salts containing heavy atoms ( $\text{AgNO}_3$ ,  $\text{Pb}(\text{CH}_3\text{COO})_2$ , NaI), sensitizers used as radiation absorbers as well as ion-exchange papers, and silica gel chromatoplates that interact with adsorbates via silanol groups or unspecific interactions. Powdered supports include sodium acetate, polymers/salt mixture, and cyclodextrins/salt mixture.

In this procedure, a microliter-scale volume of a sample is delivered to a disk of membrane support, then dried and placed in a suitable sample holder to measure the luminescent signal. In the case of powders, the analyte is added as a solution and then the solvent is evaporated. The dried residue is ground into a fine powder and placed in a phosphorescence cell or, alternatively, pressed into pellets (Figure 1).

SPLS is very sensitive and selective for organic trace analysis. Detection limits of a nanogram or even a picogram can be obtained. The methodology is simple, inexpensive, relatively precise (2–20%), relatively rapid, can handle small samples, and can be very selective in mixture analysis when solid-phase fluorescence (SPF) and solid-phase phosphorescence (SPP) are combined or when using derivative, synchronous, or time-resolved SPLS. Additionally, SPLS is well suited to being combined directly with both thin-layer and paper planar chromatography.

Drawbacks include (1) the need for some practice in sample preparation in order to obtain good results; and (2) the presence of background signals that affect detection limits and reproducibility and require the use of some means to lower these signals, such as cleaning the solid phase with polar organic solvents. Moisture and oxygen quenching affect SPP more than SPF but passing a dry inert gas into the cell compartment minimizes these problems. Additionally,

**Figure 1** Sample holders used in SPLS.

in SPP applications, the solvent used, chemical conditions of the analyte, type of solid matrix, and drying system must all be considered.

Different types of membranes such as paper, fiberglass containing C18 silica, or plasticized poly(vinyl chloride) (PVC) have also been used for pre-concentration purposes and subsequent SPF or SPP measurement. The equilibration of the membrane with the solution containing the analyte or a derivative can be carried out by adding the membrane to the solution or by filtration of the treated sample through it (solid-phase extraction). The improvement in the detection limit with respect to conventional procedures is between 100 and 1000 with a precision between 5% and 10%. Polychlorinated biphenyls from water have been preconcentrated in octadecyl-silica fiberglass, detected at subnanogram per milliliter levels and distinguished from PAHs by a combination of time discrimination and synchronous excitation techniques.

SPF and SPP can be applied in many areas such as clinical analysis, biomedical research, agricultural and pharmaceutical chemistry, energy technology, and environmental and industrial control.

A second group of procedures relies on crystallophors or phosphors that are inorganic compounds (oxide, oxyhalide, or vanadate) acting as a receptor for some luminescence activating ion (analyte), present in a very low concentration. These ions supply energy levels that are responsible for the luminescent process and from which two types can be distinguished: those that have electronic emission levels that interact weakly with the matrix (trivalent rare earth ions) and those that interact in an intense way (transition element ions, electronic configuration ions  $s^2$  (Sb(III) or Bi(III)) and most of the ions of IVB, VB, and VIB groups). The preparation of phosphor matrices that include the analyte can be accomplished in different ways such as evaporation, crystallization, precipitation, or melting. This has been used for the determination of rare earths and transition elements in minerals, industrial products, or wastewaters with very good detections limits ( $3 \times 10^{-6}\%$  of U in  $\text{SiO}_2$  or  $10^{-8}\%$  of Mn in HCl), although these are inconvenient methods considering the preparation of the matrix.

A third type of procedure integrates all the necessary reagents in one or more layers of a reactive zone (test strips). To use these systems, a drop or precise volume of a fluid problem is placed on one of the surfaces of the solid-phase element by dipping or addition, where it diffuses into the reaction zone and dissolves the reagents. After the reaction, the generated luminescent signal is measured on the device itself by means of a compact analyzer or by a fully

automatic analyzer. These test strips have been used mainly for clinical analysis.

It is possible to classify these membranes by how they relate the sample containing the analyte to the test strip; that is, into vertical and horizontal systems. With vertical systems, the fluid goes through the layer or layers that make up the reagent zone in a perpendicular way, undergoing a series of reactions and processes that make it possible to develop an analytical property. In horizontal systems (lateral flow membrane), the sample is deposited on a reception zone and is moved by fluid flow through the test strip, producing chromatographic separations, reactions, and/or analyte retentions or interferences that generate the analytical property (Figure 2).

Among the sensing schemes implemented in luminescent vertical systems are: (1) Ionophores for alkaline and alkaline earth ion determination in biological fluids. The host-guest recognition process of the analyte by the ionophore is transduced by means of a fluorescent dye incorporated in a heterogeneous monolayer membrane or in a multilayer format. (2) Enzymatic reactions for analytes of clinical interest; for example, those based on the use of a dehydrogenase, a diaphorase, and a fluorophor. Enzymatic chemiluminescent test strips have been proposed that use photographic film positioned next to the strip or include a photoresponsive imaging layer in a multilayer strip. (3) Biological recognition elements, mainly antibody/antigen reactions. Here, different heterogeneous assays have been proposed that use the prior separation of bound and free labeled components and the measurement of test strip

**Figure 2** Test strip types.

luminescence. Homogeneous assays use different label systems such as: enzyme prosthetic group labels, enzyme substrate labels, coenzyme labels, enzyme modulator labels, or quenchable fluorescent labels.

Horizontal systems have been used mainly for heterogeneous bioassay where the separation of the free and bound labeled molecules is accomplished by capillary migrations through the carrier element.

Fluorescent labels are typically small organic dye molecules, such as fluorescein, Texas Red, or rhodamine, which can be readily conjugated to probe molecules. They show problems associated with background sample, autofluorescence, and photobleaching. Some alternatives include the use of fluorescent dyes, such as phycobiliproteins, that emit in the far-red or near-infrared where nonspecific fluorescent noise is reduced. Another alternative uses inorganic luminescent materials, like down-converting phosphors (i.e., ZnS activated by Ag or  $Y_2O_3$  activated by Eu) with narrow-band emission, large downward Stokes shift ( $\geq 100$  nm), long lifetime ( $> 1$   $\mu$ s), and stability, but low quantum efficiency in aqueous solutions. Another alternative is the up-converting phosphors (i.e., rare earth doped vitrocereamics) that absorb two or more photons in a frequency that is lower than the frequency of photon emission. Since up-conversion occurs within the host crystal, the optical properties of the phosphors are unaffected by their environment.

A fourth group of SPLS procedures uses a solid phase to preconcentrate the analyte as such or as a derivative from solution and consists of the use of powdered solid supports with small-sized particles ( $\leq 100$   $\mu$ m), which are placed in contact with the sample and to which are added the reagents needed for derivatization, elimination of interferences, adjustment of conditions (pH, ionic strength, solvent, etc.), and retention on the solid phase. The collection of this solid, packed in a 1 mm quartz cell, and the direct measurement of the luminescence signal makes it possible to then quantify the analyte.

Solid supports used include ion exchangers (polystyrene and polydextran type), sorbents (hydrophilic such as polydextran type and hydrophobic such as  $C_{18}$  silica), and modified sorbents, usually chelating sorbents, either with grafted groups or loaded with chelating ligands, i.e., silica modified with lumogallion used for aluminum analysis. Interaction between the analyte and the particulated solid phase can be accomplished in several ways. Retention of the intrinsically luminescent analyte can be accomplished by ion exchange or adsorption using hydrophilic or hydrophobic sorbents, as is the case with PAHs, pesticides, and drugs such as ciprofloxacin. When derivatives are used, the derivatization of the

analyte through complex formation or organic reactions can be accomplished in solution or directly in solid phase.

In the procedure, a variable volume of the sample is equilibrated in the presence of the solid phase and reagents, if necessary, by magnetic stirring in a glass or tube or by shaking in a rotating agitator. Measurement preparation involves attaining an evenly covered layer with the solid phase. The most common procedure uses a 1 mm optical quartz cell with the solid phase packed following solid-phase filtration or decanting. The intensity of the transmitted luminescence is usually measured, for which a cell holder fixed in a position at a  $45^\circ$  angle with the excitation and emissions beam is used.

These assays can be used for organic compounds such as pesticide and metal ion trace analysis, typically in water, mainly by SSF, and show good preconcentration factors and, consequently, good sensitivity and detection limits, with an acceptable reproducibility (1–3%) and equilibration times that are generally not very long. They use less-expensive and conventional instrumentation for analysis from nanogram per liter to microgram per liter levels and do not use solvents. The selection of the solid phase, chemical conditions, and/or use of derivative, and synchronous or variable-angle scanning luminescence makes it possible to resolve mixtures, along with, on occasions, multivariate calibration. Additionally, the sensitivity of the procedures can be adjusted by modifying the volume of the sample being used. The assays are inconvenient in that they can be slower than conventional methods and require, at times, specifically prepared solid phases.

A fifth group of procedures includes the use of an array format. The usual 96-well plate for immunoassay measures the fluorescence in liquid phase either by determining the unbound fraction or by dissolving the bound reporter molecules to overcome problems related to autofluorescence, scattering, and back-reflection, although the selection of an appropriate solid support allows for the measurement of the fluorescence directly on the solid surface. For example, a heterogeneous fluoroimmunoassay using fluorescein-labeled antibodies for total thyroxine in serum uses this procedure.

The miniaturization of microplates produces high-throughput screening arrays. Microarrays (biochip) usually consist of many – from a hundred to several hundred thousand – microscopic spots containing a binding partner, such as receptors, ligands, probes, or targets, immobilized within a small and defined area on a flat solid support of glass or polymer. Each spot contains identical molecules but the array as a whole contains different molecules, according to the

requirement. Fluorescence labels are by far those most often used to detect a binding event. The sample itself is labeled at some stage before incubation. Next the array is read, usually in a dry state, giving a snapshot picture of fluorescence intensity. The most widely used luminescent detection methods in high-throughput screening arrays include laser-induced fluorescence, fluorescence resonance energy transfer (FRET), fluorescence polarization, time-resolved luminescence, and fluorescence correlation spectroscopy.

As the ambient analyte theory predicts, the miniaturization of binding assays gives rise to increased sensitivity (nanomole per liter range) with low sample consumption (submicroliter volume range) and independence from the actual volume of sample. Currently, typical screening programs operate at throughput rates on the order of 10 000 compounds per assay per day.

Different types of molecules can be used as capture molecules in microarray assays, resulting in different interaction assays. Antigen–antibody, protein–protein, aptamers, enzyme–substrate, and receptor–ligand interactions, among others, have been used in miniaturized and parallelized immunoassay for diagnosis, with great possibilities for the diagnostic market. For DNA microarrays, which are based on nucleic acid–nucleic acid interactions, presynthesized oligonucleotides, or polymerase chain reaction fragments, are immobilized on the solid support. The targets of the analysis are extracted from the cell, luminescently labeled and hybridized to their immobilized complementary capture probes and then the capture targets are measured. DNA microarrays enable the production of expression profiles and their correlation with cell function, which is useful in different fields, such as cancer. Protein microarrays or proteome chips are potentially powerful tools for comprehensive analysis of protein–protein interactions. Cell microarray also makes it possible to perform a high-throughput characterization of gene function using cell arrays involving either living cells (microwells) or printed microarrays (slides).

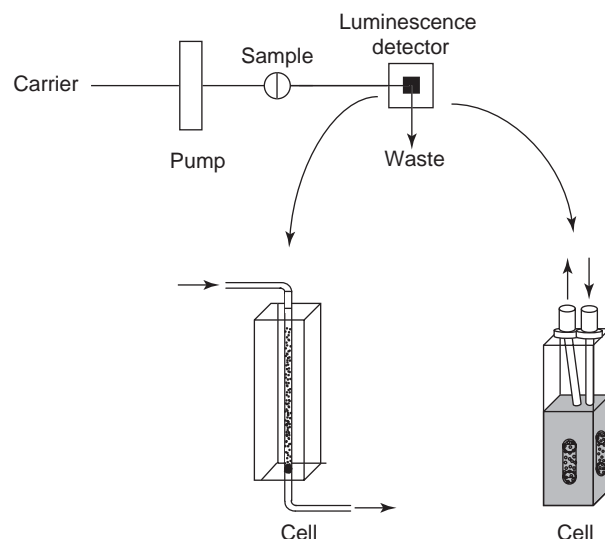

### Continuous Flow Procedures

The location of the membrane at the end of an optical fiber or the use of the flow-through cell of a FIA device with particles (usually larger than 30  $\mu\text{m}$ ) or films means an increase in the degree of integration of the procedure because the measurement stage is included with the reaction and detection and, thus, luminescent sensors can be designed. The solid phases used are widely varied and include ion exchangers, adsorbents, and organic or inorganic polymers.

Flow-through luminescent procedures have several advantages: continuous flow operation, easier automation, improved precision, and selectivity by using online separation chemistries. The drawback that water has in SPP batch procedures, especially with paper, disappears with continuous procedures, making it possible to obtain signals from aqueous flows (Figure 3).

Optical fiber (OF) luminescent sensors use an OF technology to transmit electromagnetic radiation from a sensing region that is in direct contact with the sample and contains a chemical recognition phase that generates an analyte-dependent signal. The advantages of OF luminescent systems come from their long-distance transmission, multiplex capability, immunity to electric or magnetic interference, easy miniaturization, and inherent sensitivity. The principal drawbacks are: leaching and photobleaching of dyes (photodrift), background signals from the fiber, and a long response time if a mass transfer to the membrane occurs. Various approaches have been used to solve the problem of photodrift, such as the ratiometric method, which refers the luminescent signal to the isosbestic point signal or to another analyte-dependent signal, or the use of an internal reference dye, such as the dual luminophore referencing method, wherein the analyte-sensitive fluorescence intensity signal is converted into the phase domain by coimmobilizing an inert long-lifetime reference luminophore with similar spectral characteristics. Sensing schemes based on lifetime measurement both in the frequency and time domains are more insensitive to signal drift.

The measurement schemes for intrinsic or extrinsic luminescence in FIA or OF may be similar and

**Figure 3** Luminescent optosensing manifold.

intensity, decay time, phase, or polarization can be selected as the analytical signal, although OF also offers alternatives such as the use of an evanescent wave to excite the luminescence of luminophors placed on the surface of the side of the fiber core.

Different configurations and chemistries have been used in SPLS continuous procedures with increased advantages over the batch procedures, since it is possible with the former to use systems that are not possible with the latter. The luminescence signal can be obtained from temporary or permanent immobilization of the analyte or reaction product in the solid phase in the case of flow-through systems. The sensing schemes for intrinsic luminescent analytes are not very common because of the lack of intrinsic luminophors, such as with PAH, polychlorinated biphenyls, or trinitrotoluene. It is much more common to use different sensing schemes to obtain a luminescent event from a nonluminescent analyte. Among others are

1. Conventional complex formation, mostly in ion-exchangers, for metal ions or organic complexing molecules. An example is the determination of lead in seawater with 8-hydroxy-7-quinolinesulphonic acid retained in an anion-exchange resin. An interesting option is the use of lanthanide-sensitized luminescence in SPP, as with tetracyclines. The slightly reversible character of most complexes due their high free enthalpy of formation does not make their use in OF formats possible, rather only in irreversible-reusable FIA sensors.
2. Ionophores to reversibly bind cations, anions, or organic compounds, usually incorporated in plasticized hydrophobic membranes. Different approaches for carrier-based fluorosensors are known, such as polarity-sensitive dyes based on the change induced by an analyte in the microenvironment. This is the case with the PVC membrane containing rhodamine B octadecyl ester sensitive to nitrate; other types are ion-exchange or coextraction mechanisms for cation or anions, respectively, based on the coupling, through an electroneutrality condition, of a proton exchange or extraction process highlighted by a lipophilized luminescent pH indicator.
3. Fluoroionophores that consists of a fluorophore, signaling moiety, linked to an ionophore, recognition moieties, through a spacer. The analyte recognition changes the photophysical characteristics of the fluorophore, due to electron transfer, charge transfer, energy transfer, excimer or exciplex formation, disappearance, etc. The most used types are photoinduced electron transfer and photoinduced charge transfer. They are used for cation sensing through chelator, podand, coronand, cryptand, or calixarene units, for anion sensing through hydrogen bonding or metal-ligand interactions, and for neutral analytes using fluorogenic reactants that perform reversible chemical reactions.
4. Chemiluminescent reactions through the immobilization of chemiluminescent reagents on different supports in OF or FIA format, as with the use of NADH oxidoreductase and bacterial luciferase for NADH determination at subpicomolar concentration.
5. Bioreceptor components including enzymes in combination with a luminescent indicator or reagent through a transducer such as oxygen, pH, or NADH; whole cells such as genetically engineered bacteria placed at the distal end of an OF, containing a gene-encoding bioluminescent protein that produces a bioluminescent signal in the presence of the analyte; animal or plant tissues, i.e., algal biosensors based on chlorophyll fluorescence for detection of herbicides; cell receptors, like the combination of bacterial cytoplasmic membrane and an oxygen-sensitive phosphorescent ruthenium complex for lactate detection; antibodies or antigens using auxiliary luminescent labeled reagents in a wide variety of competitive and noncompetitive assay formats.
6. Molecularly imprinted polymers (MIP) containing specific binding clefts with a predetermined size, shape, and three-dimensional arrangement of functional groups obtained by molecular imprinting with covalent or noncovalent interactions and used in different FIA or OF approaches, depending on the analyte. For intrinsically or labeled fluorogenic analytes, the measurement of bound analyte is used, as with *N*-dansyl phenylalanine using a polymer of methacrylic acid and 2-vinylpyridine. For nonluminescent analytes, different strategies are used, such as competition with a reporter molecule, alteration of wavelength, and/or intensity of a luminophore within the MIP or formation of a luminophore within the MIP.
7. FRET, which converts color changes into luminescence information, either intensity or lifetime, based on the overlap of an inert luminescent donor and the absorption spectrum of an analyte-dependent acceptor. High levels of CO<sub>2</sub> in a gas phase can be measured based on FRET between a ruthenium polypyridyl complex and the pH indicator Sudan III.
8. Twisted intramolecular charge transfer based fluorophores that involve states with high dipole moment and strong dependence of its fluorescence emission on the polarity of the microenvironment. These are useful for the determination of lower alcohols, for example, methanol or ethanol, with 4-(diethylamino)benzoic acid.
9. Quenchable luminophore based on dynamic quenching, quite used for oxygen, as well as for

heavy metal ions, humidity determination, or static quenching, as with curcumin for *o*-nitrophenol determination.

SPLS has been employed as a detection technique for high-performance liquid chromatography (HPLC), either by collecting fractions based on retention times and measuring SPF and/or SPP, as with tetrol metabolites of benzo[*a*]pyrene–DNA adducts or, alternatively, SPP can be carried out in a continuous flow mode with the aid of a two-nebulizer automatic system coupled to an HPLC system and used for the determination of caffeine, theophylline, and theobromine in the nanogram range. The use of a small flow cell loaded with a solid phase also makes HPLC luminescent detection possible. For example, terbium ions immobilized on silica have been used for the detection of nitrogen heterocycles.

## Instrumentation

Commercial instruments can be used for solid-phase luminescence by simply using a solid-phase sample holder that is available from the manufacturer or by constructing a homemade sample holder. The instrumental components are described elsewhere in the encyclopedia.

The instrumental components used for SPF are the same as those used for the measurement of solution fluorescence, although frontal cell geometry is preferred. In this way, the excited and viewed volume element moves next to the cell wall, reducing the attenuation of the signal. As light sources, arc and incandescent lamps, especially low-pressure mercury arc lamps and xenon lamps, are used, and lasers are used for steady-state or time-resolved measurements. The source radiation passes to a wavelength selection device (monochromator or filter) that selects the appropriate excitation radiation. The exciting radiation is passed to the luminophors containing the solid matrix, and from the luminescence that is emitted in all directions, a portion is collected, passed to the emission wavelength selector, and is imaged on the detector. Because the observed luminescence radiant power is usually low, the use of detectors such as photomultiplier tubes for fixed-wavelength or slow-scanning measurements is required. Complete emission spectra can be acquired rapidly with a multichannel detector interfaced to an emission spectrograph. Both intensified diode arrays and silicon-intensified target vidicons have been used (Figure 4).

To measure SPP in the absence of fluorescence and scattered radiation, it is necessary to use a phosphoroscope or a pulse-source gated detector. A phosphoroscope is a mechanical device, at present not used, that

**Figure 4** Schematic diagram of instrumental components for the measurement of SPF. S, source; M1, excitation monochromator; SP, solid phase with sample; M2, emission monochromator; D, detector. (Adapted with permission from Robert JH (1995) *Luminescence: Solid Phase*, pp. 2749–2756; © Elsevier.)

makes out-of-phase excitation and measurement of phosphorescence possible. The pulse-source gated detector makes it possible to measure phosphorescence by time resolution achieved with pulse excitation and electronically gated detection. The solid phase is repeatedly excited with radiation from a pulsed or chopped light source and the resulting phosphorescence from a given pulse is measured following a suitable delay time after the end of the pulse.

In the case of OF luminescent sensors, both traditional optical systems and all solid-state systems have been used. Instruments from this second group operate using the same principle as the conventional system, except that LEDs and laser diodes form the main light sources and the signal processing units are fully electronic systems.

The miniaturization of luminescence assay screening has led to the development of new detection instruments. So far, detection is performed principally by luminescence using charge coupled device (CCD) cameras or laser scanners with confocal detection optics. CCD cameras offer a great amount of flexibility and sensitivity for the detection of luminescent labels in parallel. Quantitative fluorescent imaging depends on the linearity of photon capture and electron release by the CCD. For medium-density arrays (spot size > 200 μm), area imaging systems are rapid and appropriate. Confocal techniques are not effectively sensitive to miniaturization because of the small size of the confocal detection volume (typically femtoliters); consequently, confocal arrangements are preferable for high spatial resolution (high-throughput screening arrays), although they are more time consuming because they focus on each dot in the whole array. A sensitive alternative to confocal detection optics regarding the signal intensity, linearity, signal-to-noise ratio, and background

**Figure 5** Schematic of data acquisition in microarray technology: (A) charge coupled device (CCD) cameras; (B) laser scanners with confocal detection optics.

is the application of planar waveguide excitation devices combined with CCD cameras or photomultipliers as detectors and based on the excitation of confined surface fluorophores by the created evanescent field (Figure 5).

This article is reproduced from the previous edition, pp. 2765–2780, © 1995, Elsevier Ltd.

### Introduction

Mankind has been fascinated by magnetism since before recorded history. Magnetic iron-containing rocks like lodestone show the attraction and repulsion of a natural magnet. Navigating via the magnetic compass was the first widespread application of magnetism, but magnetic navigation predates us by eons: ferromagnetic crystals based on an iron-oxide hydrate complex in the brains of migratory birds allow them to fly halfway around the world without getting lost even when landmarks and stars are obscured.

Everything has magnetic properties, so it is not surprising that magnetism can be used for both quantitative and qualitative analysis. Magnetic studies and data have been widely reviewed and tabulated. Because of the wide range of magnetic properties that quite similar materials can possess, it is important to know about magnetism in general before it can be used analytically. Magnetism can be used for bulk analysis, distinguishing particular elements especially different metals in compounds, and for indicating structure types. Magnetic properties are best used in conjunction with other properties, and the more is known about a sample, the more use can be made of the magnetic properties.

### Types of Magnetism

#### Diamagnetism

This is caused by orbiting electrons and is therefore a property of all matter. Applied magnetic fields induce currents in electric conductors, and this includes electron orbits and the induced currents in turn decrease magnetic field strength within the conductors. These are the shielding currents that are the basis of nuclear magnetic resonance (NMR) spectroscopy.

The effect is small compared to paramagnetism (see below) and therefore treated as a correction to be added to the observed paramagnetism, i.e., how much the observed magnetism has been decreased by the diamagnetic shielding.

The effect will depend on the number and distribution of electrons, and is therefore roughly constant for a given element. The approximate molar diamagnetic susceptibility  $\chi^{\text{dia}}$  can be calculated by taking the tabulated contributions from the known values for each element, called Pascal's constants (Table 1), and adding them up, e.g.,

$$\begin{aligned}\chi_{\text{C}_6\text{H}_6} &= 6 \times \chi_{\text{C}} + 6 \times \chi_{\text{H}} + 6 \times (\text{constitutive correction}) \\ &= -6 \times 10^{-6}(6.00 + 2.97 + 0.24) \\ &= -55.02 \times 10^{-6} \text{ c.g.s.e.m.u}\end{aligned}$$

**Table 1** Molar correction ('Pascal') constants for atoms, ions, and multiple bonds

Transition metal	– 13	N, NRR'	– 2.1
Ag	– 31.0	N, N=CR	– 2.11
Ag(I)	– 24	Na	– 9.2
Al	– 13.0	NCO <sup>–</sup>	– 21
As(III)	– 20.9	NCS <sup>–</sup>	– 35
As(V)	– 43.0	NO <sub>3</sub> <sup>–</sup>	– 20
B	– 7.0	O, R–O–	– 4.61
BF <sub>4</sub> <sup>–</sup>	– 39	O, C=O	+ 1.73
Bi	– 192.0	O, carboxy	– 3.36
Br	– 30.6	O, O <sup>2–</sup>	– 12
Br <sup>–</sup>	– 36	P	– 26.3
C	– 6.0	Pb(II)	– 46.0
Ca	– 15.9	S	– 15.0
Cl	– 20.1	Se	– 23.0
ClO <sub>4</sub> <sup>2–</sup>	– 34	Si	– 20.0
CN <sup>–</sup>	– 18	Sn(IV)	– 30.0
CO <sub>3</sub> <sup>2–</sup>	– 34	SO <sub>4</sub> <sup>2–</sup>	– 40
F	– 6.3	Te	– 37.3
F <sup>–</sup>	– 11	Tl(I)	– 40.0
H	– 2.93	Y <sup>3+</sup>	– 12
Hg(II)	– 33.0	Yb <sup>3+</sup>	– 18
I	– 44.6	Zn	– 13.5
I <sup>–</sup>	– 52		
K	– 18.5	Multiple bonds	
Li	– 4.2	–C=C–	5.5
Mg	– 10.0	–C≡C–	0.8
N, aza chain	– 5.57	–C=C– in phenyl	– 0.24
N, ring	– 4.61	–C=N–	8.2
N, NHR	– 1.54	C=N–N=C	10.2

This is in good agreement with the observed diamagnetism for benzene ( $54.78 \times 10^{-6}$  c.g.s.e.m.u.) based on data collected in the *Handbook of Chemistry and Physics*.

The tables of diamagnetic susceptibilities in the above handbook can be used to obtain even better values for appropriate molecular fragments that are contained in the paramagnetic sample. When extremely accurate corrections are needed (e.g., when the material being analyzed is a protein), it is best to make measurements on the diamagnetic chemical equivalent of the paramagnetic complex in question, e.g., the diamagnetism of a zinc porphyrin could be used to estimate the correction in the iron complex with the corresponding porphyrin ligand.

### Paramagnetism

Electrons and nucleons have angular momentum (and hence the magnetism of a moving charge) as if they had spin as well as orbital motion. Paramagnetism is due to unpaired spins. Nucleon spins, the basis of NMR spectroscopy, have a small angular momentum compared with that of the larger electrons, and is normally ignored when considering the paramagnetism arising from electrons.

Electron spins produce a large effect. For ease of consideration, the electron motion is resolved into two components.

The charged particles are too small to observe directly if they are spinning, and it is not necessary to believe that electrons spin. Dirac showed that the apparent spin is purely a relativistic effect, getting larger for the faster-moving electrons of outer orbitals. However, the real angular momentum is conveniently calculated from the (fictitious in the Dirac theory) spin component and the conventional (i.e., classical mechanical) orbital component (Figures 1 and 2). Since it is the easiest way to obtain the correct results, the convenient fiction of electron spin, used by all and believed by many, will be retained.

In Figures 1 and 2, the effect of  $S$  can be removed only by pairing an electron with another of opposite spin, so the effect is always present when there are unpaired electrons;  $L$  is sometimes quenched, depending on molecular symmetry, in which case we speak of a 'spin-only' system.

The electron spins tend to align with an applied magnetic field, but in the absence of the field, they lie in random orientation.

### Extended Magnetic Coupling

The main most important types of extended, or lattice-wide, magnetic coupling are ferromagnetism, which has spins lining up spontaneously even in the

**Figure 1** Spin angular momentum,  $S$ . Simplified view of spinning charged particle. The current loop generates a magnet.

**Figure 2** Orbital angular momentum,  $L$ . Simplified view of orbiting electron. Again the current loop generates a magnet.

**Figure 3** Line-up of electron spins in (A) ferromagnetism, (B) antiferromagnetism, (C) ferrimagnetism.

absence of an external magnetic field (Figure 3A); antiferromagnetism, which has electron spins on different atoms tending to line up antiparallel resulting in weaker magnetism (Figure 3B); and ferrimagnetism, which has two unequal ferromagnetic lattices lined up against each other, canceling out part of the effect. The last is a special kind of ferromagnetism (Figure 3C).

### Simplified Theoretical Basis

A simple theoretical consideration will indicate what it is that is to be measured.

Magnetization of a substance is defined as

$$\mathbf{B} = \mathbf{H} + 4\pi\mathbf{I}$$

where  $\mathbf{B}$  is the magnetic flux (field within the sample),  $\mathbf{H}$  is the applied magnetic field (*in vacuo*), and  $\mathbf{I}$  is the magnetization intensity or magnetic moment per unit volume.

Chemists often use the symbol  $\mathbf{H}$  in place of  $\mathbf{B}$ , but there is a difference between the two. Rearranging the terms in the equation:

$$\mathbf{B}/\mathbf{H} = 1 + 4\pi\mathbf{I}/\mathbf{H}$$

This gives  $\mathbf{I}/\mathbf{H}$ , the magnetization per unit magnetic field per unit volume, i.e., the magnetic susceptibility,  $\kappa$ , per unit volume.

The magnetic susceptibility per unit mass ('gram susceptibility'),  $\chi_g$ , is defined in terms of  $\kappa$  as

$$\chi_g = \kappa/d$$

where  $d$  is the density.

The magnetic susceptibility per mole ('molar susceptibility') is  $\chi_M = \chi_g$  (mol. wt.).

But as everything has a diamagnetic susceptibility, this must be corrected by subtracting the total diamagnetic susceptibility,  $\chi_M^{\text{dia}}$  (a negative quantity):

$$\chi_M = \chi_M^{\text{obsd}} - \chi_M^{\text{dia}}$$

The quantity most often quoted to express magnetic properties in metal complexes, the effective Bohr magneton number  $\mu_{\text{eff}}$  is defined in terms of  $\chi_M$ :

$$\chi_M = N \left( \alpha_0 + \frac{\mu_{\text{eff}}^2 \beta^2}{3kT} \right) \quad [1]$$

where  $N\alpha_0$ , the induced moment, a temperature-independent paramagnetism, is usually small and often ignored ( $\beta$  is the Bohr magneton,  $k$  the Boltzmann constant, and  $T$  the absolute temperature). (Although  $\mu_{\text{eff}}$  is often assigned the dimensions of Bohr magnetons, this is incorrect.) The magnetic moment in the field direction,  $\mu$ , is defined as  $\mu = -\partial E/\partial H$ , where  $E$  is the energy of the atom or molecule in field  $H$ .

Thus, the moment observed per mole,

$$M = N \frac{\sum_i \mu_i e^{-E_i/kT}}{\sum_i e^{-E_i/kT}}$$

based on  $i$  energy states, each with moment  $\mu_i$ . This gives

$$\chi_M = \frac{M}{H} = -\frac{N}{H} \frac{\sum_i (\partial E_i / \partial H) e^{-E_i/kT}}{\sum_i e^{-E_i/kT}} \quad [2]$$

In general,  $E_i$  can be expanded as a power series in  $H$ :

$$E_i = E_i^0 + E_i^{\text{I}}H + E_i^{\text{II}}H^2 + \quad [3]$$

which when substituted into [2] gives

$$\chi = -\frac{N}{H} \frac{\sum_i (E_i^{\text{I}} + 2E_i^{\text{II}}H + \dots) e^{E_i^0/kT} \cdot e^{-E_i^{\text{I}}H/kT} \dots}{\sum_i e^{-E_i^0/kT} \cdot e^{-E_i^{\text{I}}H/kT} \dots}$$

This is useful if it converges as it does for the 'small'  $H$  values that apply to common laboratory magnetic fields (for  $H = 1$  T (one 'tesla', the SI unit of magnetic field),  $E = g\beta H \approx 0.5 \text{ cm}^{-1}$ , while the thermal energy available at room temperature,  $kT \approx 200 \text{ cm}^{-1}$ ,  $g$ , the Lande factor, has a small numerical value, frequently close to 2).

Using

$$e^{\pm x} = 1 \pm \frac{x}{1!} + \frac{x^2}{2!} \pm \frac{x^3}{3!} + \frac{x^4}{4!} \pm \dots$$

gives

$$e^{-E_i/kT} \approx e^{E_i^0/-kT} \cdot e^{E_i^{\text{I}}/-kT} \approx e^{E_i^0/-kT} \left( 1 - \frac{E_i^{\text{I}}H}{kT} \right)$$

If, as is normally the case, there is no mean residual moment at  $H = 0$ , this gives

$$\Sigma(\mu)_{H=0} e^{-E_i^0/kT} = -\Sigma E_i^{\text{I}} e^{-E_i^0/kT} = 0$$

that is,  $\Sigma_i E_i^{\text{I}}$  always sums to zero (e.g.,  $g\beta H$  and  $-g\beta H$ ); the terms in  $H^2/kT$  are very small, so that

$$\chi_M = N \frac{\Sigma_i \left( (E_i^{\text{I}})^2 / kT - 2E_i^{\text{II}} \right) \cdot e^{-E_i^0/kT}}{\Sigma_i e^{-E_i^0/kT}} \quad [4]$$

This is the van Vleck equation, though strictly van Vleck derived the equation for the closely related electric susceptibility. Equation [4] holds for most cases encountered in the laboratory ( $g\beta H \ll kT$ ). At very large  $H$ , the approximations used in the derivation break down,  $\chi_M$  becomes dependent on the magnetic field, and paramagnetic saturation is said to be reached.

This is best illustrated by a simple example: For the spin-only  $S = \frac{1}{2}$  case, e.g., most simple copper(II) and vanadium(IV)O compounds,  $M_s = \pm \frac{1}{2}$  and  $E_i$  has only two values  $E_1 = -\frac{1}{2}\beta H$  and  $E_2 = +\frac{1}{2}g\beta H$  (Figure 4).

Figure 4  $E_i$  values for  $S = \frac{1}{2}$ .

In the format of eqn [3], these correspond to

$$E_1 = 0 - \frac{1}{2}g\beta H + 0H^2 + 0\cdots$$

$$E_2 = 0 + \frac{1}{2}g\beta H + 0H^2 + 0\cdots$$

Substituting in eqn [4],

$$\chi_M = N \frac{(-\frac{1}{2}g\beta H)^2 + (+\frac{1}{2}g\beta H)^2 \cdot e^0}{2e^0} = \frac{Ng^2\beta^2}{4kT} \quad [5]$$

It is also possible, and instructive, to derive this from eqn [2]:

$$\chi_M = -\frac{N(\partial E_1/\partial H)e^{-E_1/kT} + (\partial E_2/\partial H)e^{-E_2/kT}}{H(e^{-E_1/kT} + e^{-E_2/kT})}$$

$$= -\frac{\frac{1}{2}g\beta(e^{-\frac{1}{2}g\beta H/kT} - e^{\frac{1}{2}g\beta H/kT})}{(e^{-\frac{1}{2}g\beta H/kT} - e^{\frac{1}{2}g\beta H/kT})}$$

Using  $e^{-x} - e^x = -2x - x^3/3 - \cdots \approx -2x$  and  $e^{-x} + e^x = 2 + x^2 + \cdots \approx 2$ , this again gives eqn [5].

In the general case of spin  $S$ :

$$\chi_M = \frac{Ng^2\beta^2}{3kT}S(S+1) \quad \text{or} \quad \mu_{\text{eff}} = g\sqrt{S(S+1)} \quad [6]$$

Equations [5] and [6] show that  $\chi_M$  is inversely proportional to temperature, or  $\chi_M = C/T$  for spin-only systems. This is known as the Curie law ( $C$  is the Curie constant), and requires that  $\mu_{\text{eff}}$  be independent of temperature (see eqn [1]). Slight deviations in real systems from this behavior can be approximated with an extra temperature parameter,  $\theta$  (called the Weiss constant), in the Curie–Weiss law:

$$\chi_M = \frac{Ng^2\beta^2S(S+1)}{3k(T-\theta)} \quad [7]$$

If weak intermolecular coupling of the electrons is responsible for the deviation, a negative  $\theta$  represents a negative, or antiferromagnetic, coupling, while a positive  $\theta$  would mean ferromagnetic coupling.

$\mu_{\text{eff}}$  is readily obtained from  $\chi$  (eqn [1]):

$$\mu_{\text{eff}} = \sqrt{\frac{3k}{N\beta^2}\chi_M T} = \sqrt{7.997\chi_M T} \quad [8]$$

It is worth noting that  $\chi$  can deviate from the values predicted from the Curie law (and  $\mu_{\text{eff}}$  becomes temperature-dependent) if there is

1. Spin–orbit coupling in magnetically isolated metal centers (‘magnetically dilute material’).
2. Antiferromagnetic or ferromagnetic coupling or both involving two or more paramagnetic atoms in a cluster, without further coupling between the clusters.
3. Lattice-wide ferro- or antiferromagnetic coupling between paramagnetic neighbors.

4. Lattice-wide ferro- or antiferromagnetic coupling between clusters that already have internal coupling.

Only in case (3) is the Curie–Weiss law mathematically based as a valid approximation. However, (1), (2), and (4) also cause deviation from the Curie law and all can be approximated by the Curie–Weiss law in the high-temperature limit and it is common to obtain Weiss  $\theta$  values. This is acceptable so long as there is no pretence that the  $\theta$  value has a physical meaning (e.g., purely from mechanism (3)). More often than not, the reason for the deviation is not known.

If the number of unpaired electrons is  $n$ ,  $S = n/2$  in the spin-only case and  $\mu_{\text{eff}} = \frac{1}{2}g\sqrt{n(n+2)}$ .

For free electrons,  $g = 2.00$  (actually 2.0023 with relativistic corrections), so  $\mu_{\text{eff}} = \sqrt{n(n+1)}$ , but in real compounds,  $g$  can differ from 2, e.g., octahedral  $\text{Ni}^{2+}$ ,  $g \approx 2.2$ ;  $\text{Cu}^{2+}$ ,  $g \sim 2.1$ ,  $\text{Mn}^{2+}$  and  $\text{Fe}^{3+}$ ,  $g \approx 2.00$ . In general for transition metals, when the d-subshell is more than half-full,  $g > 2.0$ , and when less than half-full,  $g$  is close to but a little less than 2.0. This makes for a convenient determination of unpaired electron numbers. In octahedral geometry, spin-only cases are the ‘A’ and ‘E’ ground states, i.e.,  $d^3$  (e.g., chromium(III)), high-spin  $d^4$  (e.g., chromium(II)), high-spin  $d^6$  (e.g., iron(III)),  $d^8$  (e.g., nickel(II)), and  $d^9$  (e.g., copper(II)). In tetrahedral geometry,  $d^1$ ,  $d^2$ ,  $d^4$ ,  $d^6$ , and  $d^7$  are spin-only. Square planar, square pyramidal, and trigonal bipyramidal complexes are also normally spin-only.

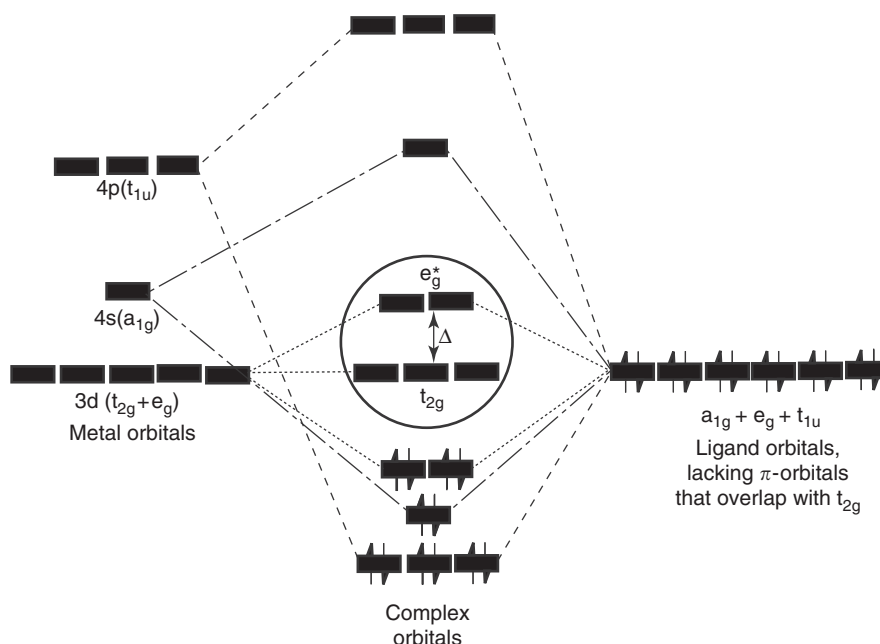

For nonspin-only cases, due to the contribution of orbital angular momentum ( $L$ ), larger (and smaller) values of  $\mu_{\text{eff}}$  may be observed, up to  $\mu_{\text{eff}} = \sqrt{4S(S+1) + L(L+1)}$ . Some specific cases are detailed below.

## Transition Metal Spin States and Magnetism

The molecular orbital diagram for even a simple octahedral complex looks complicated (Figure 5), but most of the time the information needed may be obtained by just considering the circled region, containing five orbitals:  $t_{2g}$  with threefold degeneracy and  $e_g$  with twofold degeneracy.

This is qualitatively equivalent to the results of the simpler crystal field theory, which ignores orbital overlap with the ligand orbitals and uses just the electrostatic repulsion of the metal d-orbitals and the negative charges of the ligands. Electrons in the  $t_{2g}$  orbitals are less repelled by the ligand charges, so these orbitals are lowest. The two approaches give different values for the splitting energy  $\Delta$ , which is normally determined empirically.

**Figure 5** Molecular orbital diagram for a simple octahedral complex.

For the species  $d^4$ ,  $d^5$ ,  $d^6$ , and  $d^7$  there are two choices, high spin or low spin, depending on how  $\Delta$  compares with the electron-pairing energy  $\Pi$ . If it takes more energy ( $\Pi$ ) to put two electrons into the same (lower) orbital than it takes to raise one electron into an upper orbital ( $\Delta$ ), the complex has the highest possible number of unpaired electrons or the highest value of spin ('high spin'). The configurations are:

high spin:

$$(d^7) t_{2g}^5 e_g^2, {}^4T_{1g}; \quad \frac{\text{CFSE}}{\Delta} = -\frac{4}{5}$$

$$(d^6) t_{2g}^4 e_g^2, {}^5T_{2g}; \quad \frac{\text{CFSE}}{\Delta} = -\frac{2}{5}$$

$$(d^5) t_{2g}^3 e_g^2, {}^6A_{1g}; \quad \frac{\text{CFSE}}{\Delta} = -\frac{0}{5}$$

$$(d^4) t_{2g}^3 e_g^1, {}^5E_g; \quad \frac{\text{CFSE}}{\Delta} = -\frac{3}{5}$$

where CFSE is the crystal-field stabilization energy.

The other oxidation states have only a single spin state to choose from:

$$(d^8) t_{2g}^6 e_g^2, {}^3A_{2g}; \quad \frac{\text{CFSE}}{\Delta} = -\frac{6}{5}$$

$$(d^9) t_{2g}^6 e_g^3, {}^2E_g; \quad \frac{\text{CFSE}}{\Delta} = -\frac{3}{5}$$

$$(d^3) t_{2g}^3, {}^4A_{1g}; \quad \frac{\text{CFSE}}{\Delta} = -\frac{6}{5}$$

$$(d^2) t_{2g}^2, {}^3T_{1g}; \quad \frac{\text{CFSE}}{\Delta} = -\frac{4}{5}$$

$$(d^1) t_{2g}^1, {}^2T_{2g}; \quad \frac{\text{CFSE}}{\Delta} = -\frac{2}{5}$$

$d^0$  (e.g., vanadium(V), titanium(IV), scandium(III)) and  $d^{10}$  (e.g., palladium(0), platinum(0), gold(I), copper(I), zinc(II)) are the simplest to consider. With empty and filled d-shells, respectively, they have no magnetic properties, no CFSE, and no ligand field spectra, as in nontransition metal complexes. There are some other special cases: low spin iron(II), cobalt(III), and their analogs in the second and third transition series are  $d^6$ , and are also diamagnetic. This makes cyano complexes like  $\text{Fe}[(\text{CN})_6]^{4-}$  and pyrite ( $\text{FeS}_2$ ) magnetically uninteresting, unlike high-spin iron(II), cobalt(II), and iron(III), and low-spin iron(III), which are often characterized by their magnetic properties.

High-spin manganese(III) and iron(III), having no CFSE, resemble the nontransition metals in having no preferred geometry. This enhances their ability to replace nontransition metal ions of similar size in minerals and complexes. An example is in ferrites,  $\text{M(II)Fe(III)}_2\text{O}_4$ , where the spinel structure is generally preferred, except that when M(II) is  $d^{6-9}$ , the inverse spinel structure is stabilized, with all the M(II) in octahedral sites (CFSE) and the iron(III),

**Figure 6** Orbitals in octahedral complexes.

having no geometry preference, distributed equally over octahedral and tetrahedral sites. This enables strong magnetic coupling between the iron(III) in the octahedral and tetrahedral sites: hence,  $\text{MnFe}_2\text{O}_4$ ,  $\text{CoFe}_2\text{O}_4$ , and  $\text{NiFe}_2\text{O}_4$  have moments near the 6, 5, and 3 BM values expected for high-spin manganese, cobalt, and nickel, respectively, while  $\text{MgFe}_2\text{O}_4$  has a moment approaching the zero value for manganese.

Tetrahedral complexes can be treated in a similar manner to octahedral. Both octahedra and tetrahedra are cubic systems: in octahedral complexes (**Figure 6**) the ligands occupy the centers of the six faces of a cube. In tetrahedral complexes the ligands are diagonally across the cube faces from each other (**Figure 7**), so that the d-electron repulsion by ligands works in exactly the opposite sense, giving rise to exactly the inverse picture for the orbital energies to that for the octahedral case. The  $t_2$  orbitals point closer to the ligands, and are therefore more unfavorable places for electrons to occupy, than the  $e_g$  orbitals. The subscript g, for even parity, applies to undistorted octahedral, but not to tetrahedral geometry (no center of inversion) and is therefore dropped for tetrahedral. By visualizing energy in the inverse direction, the ground state for octahedral  $d^n$  is seen to be the same as that for tetrahedral  $d^{10-n}$ . The state symbols and CFSE formulas also apply as given, except that low-spin tetrahedral complexes tend not to occur: this would require a rigid ligand with donor atoms locked in tetrahedral geometry and a large value of  $\Delta_t$ . Otherwise, any four-coordinated complex with  $\Delta$  large enough to cause spin pairing would

also distort to planar, which offers a much larger CFSE.

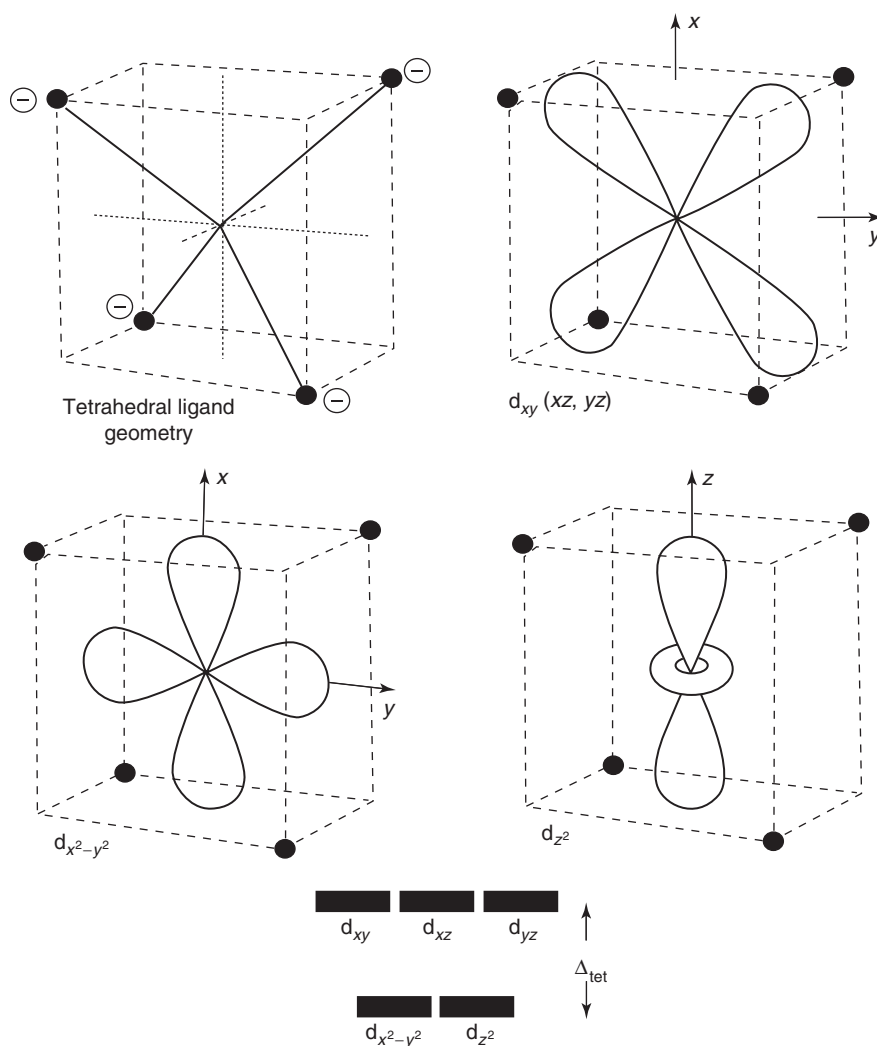

The value of  $\Pi$  does not vary much within complexes within the same transition series, but the size of  $\Delta$ , the ‘strength of the ligand’, varies widely. One way to estimate it is from d–d transitions, or ligand field spectra (hence the name, spectrochemical series):

This list gives an approximate indication of relative ligand field strength, but other factors, such as different geometries, also affect the actual crystal field experienced. In general, ligands before ‘en’ in the list do not produce low-spin compounds with iron, while those listed to the right of it do. Manganese(III) is harder to spin-pair, though  $\text{CN}^-$  does so.

## Methods of Measurement

According to what magnetic properties are to be measured and budgetary constraints, a variety of experimental techniques are available. If amount of sample is no limitation, the Gouy method is the cheapest to set up. In many cases, measurements at a single temperature cannot give unambiguous information, so variable temperature capability must be considered. The simplest quantity to measure is the force on a sample in the presence of a magnetic field.

**Figure 7** Orbitals in tetrahedral complexes.

### Gouy Balance

The Gouy method is the classical one and the easiest to set up. It is based on the apparent increase in mass of a sample hung above the axis of a magnetic field. The mass (sample plus holder) is determined by hanging the sample just over the magnetic field axis of an electromagnet that can be turned off or a permanent magnet that can be moved away (**Figure 8**). The upper end of the suspending chain attaches to a balance. The force is given as the apparent mass difference for field on and field off. The measurements must be made with the holder empty and then full of sample. The advantage is that sample mass is determined at the same time.

The force is given by the gradient of the magnetic field energy,

$$\mathbf{F} = \nabla \left( \frac{1}{2} \int_0^V K H^2 dV \right) \quad [9]$$

For a uniform sample in a tube of constant cross-sectional area  $A$ :

$$F = \frac{1}{2} \kappa A \nabla \int_0^L H^2 dz = \kappa A \int_0^L \frac{dH^2}{dz} dz = \kappa / B$$

where  $B$  is a constant of the experiment, provided the magnetic field is kept constant and the same sample tube, filled to the same point, is always used.

As  $F$  is always in the same direction, it need not be treated as a vector, and its value is the mass difference  $F_{\text{obs}} - F_{\text{empty tube}}$ .

Then  $\kappa = BF = \chi_g d$ , in a vacuum, or to good approximation in nitrogen gas. In air a correction for the paramagnetism of oxygen should be made:

$$\kappa_{\text{true}} = \kappa_{\text{obs}} + \kappa_{\text{air}}$$

i.e.,

$$\chi_g = \frac{BF + \kappa_{\text{air}}}{d}$$

**Figure 8** Schematic view of Gouy method.

This is one of the reasons why magnetic measurements are often made in gases containing no oxygen. For very accurate measurements, even the diamagnetic susceptibility of any surrounding gas must be taken into account.

If the sample tube is always filled to the same point,  $V$  is constant, and

$$\chi_g = \frac{BF}{(m/V)} = \frac{B'F}{m}$$

Calibration may be carried out with a known standard, e.g.,  $\text{HgCo}(\text{NCS})_4$ , for which  $\chi_g = 10.44 \times 10^{-6}$  c.g.s.u. at  $25^\circ\text{C}$ :

$$B' = \frac{\chi_{g(\text{std})} m_{\text{std}}}{F_{\text{std}}}$$

Then

$$\chi_{g, \text{sample}} = \frac{\chi_{g(\text{std})} m_{\text{std}} F_{\text{sample}}}{F_{\text{std}} m_{\text{sample}}}$$

The apparatus may be designed for variable temperature measurements by surrounding the sample area with a copper tube surrounded by a heater and by coolant liquid. Liquid nitrogen is the most convenient coolant. Lower temperatures may be achieved by pumping but because of the relatively large sample volume, other techniques are more convenient for temperatures down to liquid helium.

The Gouy apparatus is the easiest to make inexpensively. The main components are the magnet and a balance set up to weigh below the standard balance pan. Refinements to the setup include a transparent enclosing tube to shield the sample container and the chain supporting it against air currents. The apparatus can also be constructed for high precision. **Figure 9** shows a simple but moderately high precision setup that includes a metal (preferably copper) central tube. Holes cut on opposite sides in this make it

**Figure 9** Gouy apparatus between magnet poles.

effectively transparent; grooves on this support windings of heating wire, and the high conductivity and heat capacity of the metal enhance thermal stability by smoothing out thermal spikes. The setup shown includes a ferromagnetic shield to allow measurements on shorter samples.

The ferromagnetic shield makes the outer assembly unstable to movement toward either pole face, requiring a stronger clamping arrangement. A pair of clamps, separated by a few centimeters, is best. Here brass collars are tightened around the metal tube with strong brass rods embedded in the collar. **Figure 10** shows the individual parts of the setup.

In particular, **Figure 10F** shows the collars and rods used to clamp the metal assembly in a rigid position. **Figure 10G** shows the glassware cryostat, and **Figure 10H** the balance mounting.

The effect of changing the shapes of the magnet poles is shown in **Figure 11**. A slight conical shape gives a higher field at the center but the rate of decrease with distance away from the center is less. The optimal choice is the conical shape but with a ferromagnetic shield to decrease the field strength away from the poles more rapidly.

With large samples, the Gouy method can be very accurate, but this can also be a disadvantage when

**Figure 10** Individual parts of a Gouy balance set-up: (A) metalwork section; (B) copper tube; (C) ferromagnetic shield; (D) steel cylinder (nonmagnetic); (E) supporting pipe; (F) two brass collars with supporting rods; (G) glass flasks; (H) balance mounting. *Bottom layer* is bolted to the table. The 2.5 cm hole continues through the table and into the sample compartment. Four metal flanges house two adjustment screws each. The adjustment screws can be used to move or to clamp the *top layer* when it is in the desired position. The *top layer* slides freely on the bottom layer, except when clamped by the adjustment screws. The balance rests on the top layer, with three circular recesses to accommodate the balance legs (A, B, C, 0.5 cm deep). The 13 cm hole is required to accommodate the attachments to the balance pan. When the balance has been centrally positioned, minor adjustments may be made to the position with the adjustment screws, without dismantling.

**Figure 10** (Continued).

large samples may not be available. A range of sample tubes is normally calibrated in preparation for a variety of sample sizes. Packing of the sample must be very uniform.

The sample must be large enough to fill at least a thin sample tube, though thin tubes make uniform packing more difficult. The tube must be long enough to allow a large drop-off in magnetic field over the

**Figure 11** Effect of changing the shapes of the magnet poles.

length of the tube, since the method relies on the maximum magnetic field at the lower end of the sample tube and zero at the top. The use of a ferromagnetic shield at the top allows for a faster drop-off in field, so that a shorter sample tube can be used.

The method is also good for solution samples where the packing problem is eliminated, though the dilution of a complex in solution correspondingly reduces accuracy. For this the high-precision version of the Gouy method is preferable. It can even be used for protein solutions where the paramagnetism is very small relative to the molecular weight.

The Gouy balance can readily be adapted for high-pressure measurements. In this case, the high-pressure sample tube ('bomb') must be made of mechanically strong, but weakly magnetic material, e.g., beryllco-25 alloy. The sample, normally in solution, is pressurized in the tube, locked, and put in the Gouy balance.

### The Faraday Method

The Faraday method relies on the use of a point sample in a highly nonuniform magnetic field so that the paramagnetic sample is pulled to the strongest point. The high magnetic field gradient is achieved by unsymmetrically shaped pole faces (Figure 12).

Again using eqn [9] and the fact that  $V$  is very small:

$$F = \nabla\left(\frac{1}{2}KVH^2\right) = \frac{1}{2}KV\frac{\delta H^2}{\delta z} = \chi_g m \frac{\delta H^2}{\delta z} = \chi_g m/B'$$

**Figure 12** Faraday method with magnet poles designed to produce a highly nonuniform field.

where  $B'$  is a constant of the experiment. This leads to the same equations as for the Gouy balance above. Calibration is carried out with a known sample as above. In this method, the small sample size makes it imperative that the sample chosen to put in the Faraday bucket is representative. Because both the sample and the force on it are small, an electrobalance is normally used. Very high accuracy can be achieved, but because the method relies on approximating a point sample, it cannot be scaled up much to improve accuracy on a weakly magnetic sample. Ideally, the sample should correspond to a point but in practice a sample size of a few milligrams is commonly used. Variable temperature measurements can be made by a variation of the cryostat described for the Gouy balance.

### Alternating Force Magnetometer

An advance over the Faraday method is to use induction coils, instead of specially shaped pole faces, to produce the large magnetic field gradient. The field gradient can then be varied independently of the static magnetic field, and can be reversed by reversing the current. The direction of the field gradient may be alternated periodically with respect to the static field, and the force detection passed through a phase-sensitive detector to decrease noise and improve accuracy. A variable temperature capability can be added as with the Faraday method.

### Evans NMR Method

This uses the shift  $\Delta H/H (= A\nu/\nu)$  in the NMR signal of a standard sensor, e.g., *t*-butanol, caused by a paramagnetic sample over the shift normally experienced by the sensor in the magnetic field alone (Figure 13).

Two concentric sample tubes are used, one of which contains the paramagnetic sample. Both

**Figure 13** Evans method.

contain the tensor. The volume susceptibility  $\Delta\kappa$  represents the increase in paramagnetism in the presence of the sample. This method is very convenient for determination of solution magnetism. Disadvantages are that only temperatures available to the NMR apparatus can be used and the accuracy is reduced to the proportion that the paramagnetic compound constitutes of the total solution.

### Induction Magnetometer

Insertion of a magnetic material into a conducting coil ( $n$  turns, area  $A$ , and length  $S$ ) induces a voltage  $V$  given by

$$V = \frac{pn^2 A}{S} \frac{di}{dt}$$

where  $di/dt$  is the alternating current frequency. The sample permeability,  $p$ , is related to  $\chi$  by  $p = 1 + 4\pi\chi$ . When the alternating frequency is high enough, the sample magnetization lags behind. The lag may be expressed as a phase angle  $\phi$ . If there is a fixed field  $H$  on which is superimposed an oscillation  $H_1$ , frequency  $\omega$ , such that  $H(t) = H + H_1 \cos \omega t$ , the resulting magnetization is  $M(t) = M + M_1 \cos(\omega t - \phi)$ .

### Vibrating Sample Magnetometer

This method uses the dipole field setup by an oscillating magnetic sample in a uniform magnetic field. The sample oscillation is driven by a loudspeaker that vibrates a sample holder rod, the other end of which moves the sample between the magnet poles. A permanent magnet reference sample is vibrated on the same rod. Separate induction coils, oriented with their axes parallel to the vibration monitor to allow phase-sensitive detection, monitor the sample and reference. Only a relatively small sample can be placed fully within a uniform field, but measurements on small single crystals are readily made with this apparatus. Measurements on anisotropic crystals can be made by remounting the crystal to vary the orientation with respect to the sample rod.

Limits of accuracy of commercial instruments are  $\sim 10^{-5}$  c.g.s.e.m.u.

### SQUID Magnetometer

A SQUID (superconducting quantum interference device) consists of a superconducting loop with a weak link through which current continues to flow by quantum mechanical tunneling. The SQUID is very sensitive to small changes in magnetic field, e.g., due to the approach of a paramagnetic sample to produce a sample-dependent change in magnetic flux. This signal is magnified to give the most accurate of all techniques for measuring magnetic susceptibility. The accuracy is frequently described in terms of fractional change of a fluxon (individual line of magnetic force) and the only ultimate limitation is the Heisenberg uncertainty principle. Because of the high sensitivity ( $10^{-12}$  c.g.s.e.m.u.), it is common practice to shield the magnetometer, e.g., with mu-metal around the SQUID, sample, and cryostat assembly. The optimal design has a SQUID coupled inductively to a superconducting detecting loop into which the sample is inserted (Figure 14). The overall design of a SQUID magnetometer used in the author's laboratory is shown in Figure 15.

As the SQUID measures changes in magnetic flux, it is possible to measure either a sample with fixed magnetic moment, which must be moved into or out of the detector region, or a sample with varying moment. The latter would be held in place while the perturbing influence, e.g., pressure, temperature, light excitation, chemical reaction, is allowed to change the magnetic moment. The SQUID response time is limited by the frequency (normally RF) used in the detection circuit, which readily allows the study of magnetic transients of less than 1 ms, but faster response times are being produced for shorter-lived transients.

### Applications

Sometimes magnetic properties constitute supplementary information to support other data such as microanalyses. However, by establishing how magnetic properties relate to structure they can be used in cases where structural information cannot be obtained in other ways. An example is the determination of the nature of the active sites in metalloenzymes: nearly half the important enzymes contain one or more transition metals at the active site. Because of the large molecular weight, it is frequently impossible to determine how many metal atoms there are from simple chemical analysis. This was the case with the purple acid phosphatase (p.a.p.) series.

**Figure 14** A SQUID coupled inductively to a superconducting detecting loop into which the sample is inserted.

**Figure 15** Schematic outline of a SQUID magnetometer.

The p.a.p. from animal sources was thought to contain one Fe per molecule by Aisen *et al.* (rounding down from an analysis of 1.3) and by Zerner *et al.* to contain two iron atoms (rounding up from 1.6) based on the same bulk iron analysis result within experimental error. Knowledge of the number of iron atoms present is important in understanding the function and mechanism of the enzyme, author's measurements on this system were predicated on the assumption that if there were two iron atoms the magnetism would be twice as great than if only one iron were present. Surprisingly, the magnetism was

much less than expected for either case, from which it became clear that iron is present but in a very specific way, viz., two magnetically coupled iron atoms linked as Fe(III)–O–Fe(III) (eqn [10], with  $S = 5/2$ ):

$$\chi_M = \frac{Ng^2\beta^2}{3kT} \cdot \frac{\sum_s S(S+1)(2S+1)e^{-E(S)/kT}}{\sum_s (2S+1)e^{-E(S)/kT}} \quad [10]$$

Thus, the magnetic technique not only gave the correct amount of iron but also showed the essential structural feature. The strong magnetic coupling requires that there be no electron spin resonance (ESR) spectrum, yet the enzymes had previously been characterized via ESR. The so-called characterizing spectrum was due to the presence

$$\chi_M = \frac{N\beta^2 \cdot \left[ (S+1)(2S+3)(2Sg_1+g_2)^2 + \frac{8}{x}S(S+1)(g_1+g_2)^2 \right]}{12(2S+1)kT[(S+1)e^x + S]} \quad [11]$$

of a ubiquitous impurity and in this case the magnetic technique is far superior to another (highly sensitive) analytical method (ESR).

When one Fe is replaced by copper(II), the magnetic behavior (eqn [11]) is rather similar to what is observed for another enzyme, cytochrome oxidase (Fe–Cu). Where  $g_1$  and  $g_2$  apply to the copper and iron, respectively, the spin  $S$  for iron would be  $5/2$  in the normal iron(III) state, or  $2$  for iron(II). When one of the irons is replaced by a zinc(II), the magnetism increases strongly, corresponding to a single iron(III), (zinc(II), having no d electrons, contributes nothing) and its behavior conforms to eqn [6], the Curie law. The Zn–O–Fe form still works as a normal enzyme on its substrate. This is very significant because the vegetable acid phosphatase (from kidney beans) analyses for iron and zinc and has Curie law magnetism, implying a Zn–O–Fe center. When the zinc is replaced with iron it behaves like the animal form, and also still works on its substrate; nature had long ago done the metal substitution experiment.

Again, the enzyme urease was found to contain a dimeric nickel(II) center based only on its magnetic properties (eqn [10] with  $S = 1$ ). In large proteins such as ferritin, strong coupling is seen in a Fe–O–phosphate center, rather like a small piece of rust enclosed in a protein sheath. Likewise, nitrogenases contain a number of linked irons.

The use of magnetism in studies of minerals and transition metal complexes is alluded to above. Individual metal atoms reveal their presence and bonding environment (planar, tetrahedral, etc.,

including distortion) in their  $T$ -dependent magnetic properties – deviation from Curie–Weiss (eqn [6]).

$$\chi_M = \frac{Ng^2\beta^2}{3kT} \cdot \frac{(S+1)(S+2)(2S+3)x + S(S+1)(2S+1)y + S(S-1)(2S-1)}{(2S+3)x + (2S+1)y + (2S-1)} \quad [12]$$

$$\chi_M = \frac{Ng^2\beta^2}{12kT} \cdot \frac{(2S+3)(2S+5)(S+2)a + (2S+1)(2S+3)(S+1)b + S(2S-1)(2S+1)c + (2S-3)(2S-1)(S-1)}{(S+2)a + (S+1)b + Sc + S-2} \quad [13]$$

Magnetic coupling, lattice-wide, is likewise revealed by  $\chi$  versus  $T$  dependence, and this shows how closely the metals are linked. This is a large subject, beyond the scope of this article.

Many systems have small-scale linkages where just two or three metals link in a molecule. Typical examples are copper dimers. Thus, the magnetic susceptibility of copper(II) acetate deviates dramatically from the Curie law. It was analyzed as a binuclear rather than monomeric structure long before X-ray crystallography confirmed this. Up to a third of copper(II) compounds are now known to have some such magnetic linkage that can be analyzed as ligand bridging.

Current interest in advanced, or twenty-first century, materials makes coupling between transition metals and lanthanoids important, so that highly magnetic centers (large  $S$  values) must be considered.

For example, for an ( $S=1$ ) metal coupling with another metal having a spin  $S$  of at least 1 (i.e.,  $S_1=1$  and  $S_2=S>\frac{1}{2}$ ), the magnetism is described by eqn [12] where  $x = e^{(2S+4)J/kT}$ ,  $y = e^{2SJ/kT}$ .

In a  $\text{Ni}^{\text{II}}\text{--Co}^{\text{II}}$  ( $S=3/2$ ) system, eqn [12] becomes

$$\chi_M = \frac{Ng^2\beta^2}{4kT} \cdot \frac{35e^{8J/kT} + 10e^{3J/kT} + 1}{3e^{8J/kT} + 2e^{3J/kT} + 1}$$

For an ( $S=3/2$ ) metal coupling with another metal having a spin  $S$  greater than 1 (i.e.,  $S_1=3/2$  and  $S_2=S>1$ ), the magnetism is described by eqn [13] where  $a = e^{(6S+3)J/kT}$ ,  $b = e^{4SJ/kT}$ ,  $c = e^{(2S-1)J/kT}$ .

For example, in coupling an  $S=3/2$  transition metal with an  $S=3$  lanthanoid, eqn [13] becomes

$$\chi_M = \frac{Ng^2\beta^2}{4kT} \cdot \frac{165e^{21J/kT} + 84e^{12J/kT} + 35e^{5J/kT} + 10}{5e^{21J/kT} + 4e^{12J/kT} + 3e^{5J/kT} + 2}$$

From the strength of coupling and the shape of the curve we can discriminate between different molecular forms. Each metal pair has its own characteristic signature: the  $\chi$  versus  $T$  curves represented by these equations can discriminate reliably between the different centers represented. Accurate measurement gives the strengths of coupling ( $J$ -values), which

indicate how strong the link is between the metals, e.g., a single atom bridge or a larger bridge like an

imidazole or carboxyl group. This even discriminates between different types of one-atom bridges, e.g., the oxidized form of p.a.p. has strong coupling  $J$  ( $-80\text{ cm}^{-1}$ ) due to  $\text{Fe(III)–O–Fe(III)}$  whereas the reduced form has much weaker coupling ( $-20\text{ cm}^{-1}$ ) indicating an OH bridge (having weaker Fe–O links and therefore weaker orbital overlap).

## Introduction

Mass spectrometry (MS) is an analytical technique that is used to identify unknown compounds,

quantify known materials, and elucidate the structural and physical properties of ions. The technique is associated with very high levels of specificity and sensitivity, somewhat offset by a high degree of technical complexity. Analyses can be accomplished with minute quantities – sometimes less than picogram ( $10^{-12}$  g) amounts of material. MS is highly suited to the identification of individual components in extremely complex mixtures.

The history of MS began when the existence of electrons and ‘positive rays’ was demonstrated by J.J. Thomson in the early part of the twentieth century. Thomson suggested that the technique could be used to perform chemical analysis, but this was not realized for several decades. MS was initially used to determine the relative abundances of gaseous isotopes and to measure their ‘exact masses’, i.e., atomic masses with a precision of 1 part in  $10^6$  or better. These fundamental measurements led to developments in a wide range of physical sciences.

## Principles

A mass spectrometer is an instrument that separates charged atoms or molecules according to their mass-to-charge ( $m/z$ ) ratio. The unit of mass used is the unified atomic mass unit (symbol u), defined as 1/12 of the mass of a single atom of the isotope of carbon-12 ( $^{12}\text{C}$ ). The term Dalton (Da) has become widely accepted in MS as the unit to represent atomic mass. The charge on an ion is denoted by the integer number ( $z$ ) of the fundamental unit of charge, the magnitude of the charge of an electron. In many cases, the ions encountered have just one charge ( $z = 1$ ) so the  $m/z$  value is numerically equal to the molecular (ionic) mass in Daltons. Mass spectrometrists sometimes refer to the ‘mass of an ion’ when they really mean the  $m/z$  ratio. The name Thomson (Th) has recently been proposed as a unit of mass-to-charge ratio in an attempt to alleviate the confusion caused by the increasing importance of multiply charged ions in MS, but does not yet enjoy widespread acceptance.

Formation of gas-phase sample ions is an essential prerequisite to mass selection and detection. Ions are produced and are accelerated toward an analyzer region that is maintained under vacuum. Either positive or negative ions are selected for analysis. In many cases a high proportion of the molecules do not ionize and are simply pumped away and not detected.

The sample, which may be a solid, liquid, or vapor, enters the vacuum chamber. Early mass spectrometers required a sample to be gaseous, but the applicability of MS has been extended to include samples in liquid solutions or embedded in a solid matrix.

The analyte may already exist as ions in solution, or it may be ionized by a variety of methods within the ion source.

Gas-phase ions are separated in the mass analyzer according to their mass-to-charge ( $m/z$ ) ratios and impinge on a detector, where the ion flux is converted to a proportional electrical current. A data system records the magnitude of these electrical signals as a function of  $m/z$  and converts this information into a mass spectrum, a graph of ion intensity as a function of mass-to-charge ratio, often depicted as simple histograms.

The mass scale is calibrated by introducing a reference compound that yields a well-characterized mass spectrum comprising known masses at suitable intervals. A range of calibrants is available for various techniques and applications.

## Compound Identification

The mass spectrum will typically establish the molecular weight and structure of the compound being analyzed. Mass spectra recorded under controlled conditions are highly reproducible such that the spectrum derived from an unknown may reasonably be compared to that of an authenticated standard. When combined with a chromatographic technique mass spectral identification is often regarded as providing unequivocal characterization of a chemical compound.

Large databases or libraries of spectra are commercially available to assist in compound identification in a range of applications, although currently these are largely restricted to electron ionization (EI) spectra.

Since the rules governing the fragmentation of ions in the gas phase are well established, it is also possible to elucidate the structure of an unknown compound solely from its mass spectrum.

## Quantification

Quantification may be achieved by comparing the response of the mass spectrometer from an analyte of interest to the response obtained from the introduction of a known amount of a standard. Standards are typically a closely related substance or may be chemically identical but synthesized by substituting an isotope of one of the elements.

Since the identity of the analyte is already known and the requirement is to measure how much is present, it is not necessary to record the full mass spectrum. Selected ion monitoring (SIM) is often used in such circumstances, where the mass spectrometer (generally coupled with a chromatographic technique) monitors only the sample ion and the

equivalent ion for a suitable internal standard. In this way, very selective conditions for quantifying a known sample can be devised.

### Resolution

The ability of a mass spectrometer to distinguish between ions of different mass-to-charge ratio values is termed as resolution. There are many definitions, depending on specific applications and instrument types being used. Traditionally, multisector mass spectrometers are considered as high-resolution instruments and quadrupole instruments as medium resolution.

A typical multisector instrument can be set to resolve ions at the 20 parts per million level, that is to say an ion of mass-to-charge ratio 500.00 can be separated from an ion of  $m/z$  500.01. Time-of-flight (TOF) instruments can also attain or exceed this resolution.

Exact mass measurement can aid in determining chemical composition. Every isotope (except carbon-12 which is assigned exactly 12.000 00 Da) has a unique, noninteger mass. Exact mass measurement thus allows determination of chemical composition. With sufficient resolution it is possible to distinguish between carbon monoxide (CO, 27.995 Da) and nitrogen ( $N_2$ , 28.006 Da) by exact mass measurement.

## Mass Analyzers

### Sector Field Instruments

Magnetic sectors deflect the trajectories of ions into circular paths of radii that depend on the

momentum-to-charge ratios of the ions. Ions of larger  $m/z$  values follow larger radius paths than ions of smaller  $m/z$  values, so ions of differing  $m/z$  values are dispersed in space. By changing the ion trajectories through variations of the magnetic field strength, ions of different mass-to-charge ratios can be focused onto a detector.

Double focusing sector field instruments incorporate a combination of electromagnetic fields ( $B$ ) and electric fields ( $E$ ).

A common configuration ('forward geometry') for a sector instrument is the geometry in which a magnetic sector follows an electric sector analyzer (ESA). This 'double focusing' combination of energy focusing and 'angular' or 'directional' focusing and energy focusing provides mass resolution high enough to separate ions of the same nominal mass but different chemical formulas. In 'reverse geometry,' the magnetic sector precedes the electric sector. **Figure 1** shows a reverse-geometry mass spectrometer coupled to a gas chromatograph (GC). Such instruments are commonly used for the highly specific detection of environmental contaminants such as dioxins or performance-enhancing drugs in athletes.

### Quadrupole Filters

Quadrupole mass filters consist of four parallel rods, illustrated in **Figure 2**. In such instruments, mass selection depends on ion motion resulting from simultaneously applied DC and RF electric fields. Scanning is accomplished by systematically changing the field strengths, thereby changing the  $m/z$  value that is transmitted through the analyzer. Quadrupole mass

**Figure 1** Photograph and schematic diagram of a modern 'reverse geometry' mass spectrometer coupled to a GC. (Reproduced with permission from Thermo Electron (Bremen).)

**Figure 2** Schematic diagram of quadrupole and ion trap mass analyzers.

spectrometers provide lower resolution than double focusing instruments but are less costly. The high scan speeds of quadrupole mass filters render them highly suited for use in combination with chromatographic inlet systems.

### Ion Traps

Ion trap mass spectrometers operate on a principle similar to a quadrupole mass filter. However, it does not operate as a filter; the ions are stored for subsequent experiments and analysis. Electric fields are applied to electrodes arranged as a ring electrode in the middle with cap electrodes on each end. Conceptually, an ion trap can be considered as a conventional quadrupole folded on itself to form a closed loop. A comparison with a quadrupole mass analyzer is shown in **Figure 2**. Within a selected range of  $m/z$  ratios determined by the applied voltages, the device traps ions in the space bounded by the electrodes. A mass spectrum is produced by scanning the applied RF voltages to eject ions sequentially of increasing  $m/z$  ratio through an end cap opening for detection.

### Fourier Transform Mass Spectrometry

In a Fourier transform ion cyclotron resonance (FT-ICR) spectrometer, ions are trapped electrostatically within a cell in a constant magnetic field. An orbital ('cyclotron') motion is induced by the application of a pulse between the exciter (or emitter) plates. The orbiting ions generate a faint signal in the detector (or receiver) plates of the cell. The frequency

of the signal from each ion is equal to its orbital frequency, which in turn is inversely related to its  $m/z$  value. The signal intensity of each frequency is proportional to the number of ions having that  $m/z$  value. The signal is amplified and all the frequency components are determined, yielding the mass spectrum. Since the pressure in the cell is very low, the ion orbital motion can be maintained over many cycles and the frequency can be measured with very high precision. FT-ICR instruments can therefore be used to generate exceptionally high resolution spectra with great mass accuracy.

### Time-of-Flight Mass Spectrometry

TOF mass analyzers separate ions by virtue of their different flight times over a known distance. Pulses of ions are ejected from a source and accelerated so that ions of like charge have equal kinetic energy. They are then directed into a flight tube where lower mass ions have greater velocities and shorter flight times. The travel time from source to detector can be transformed to the  $m/z$  value. All ion masses are measured for each pulse, so TOF mass spectrometers offer high sensitivity as well as very rapid scanning. They can provide mass data for very high-mass biomolecules.

### Ionization Methods

Compounds are converted into gas-phase molecules either before or during the charging or ionization process, which takes place in the ion source.

Many types of ionization mode are available; the type of compound to be analyzed and the specific information required determine which ionization mode is the most suitable. The ionized molecule may subsequently fragment, producing ions of lower mass than the original precursor molecule. These fragment ions are determined by the structure of the original molecule.

### Electron Ionization

In the commonly used EI source (earlier referred to as 'electron impact'), ions are generated by bombarding the gaseous sample molecules with a beam of energetic electrons. EI produces a mixture of positive and negative ions, as well as neutral species. Positive-ion EI mass spectra are more commonly recorded because these ions form more readily.

The energy of the electrons (typically 70 eV) is generally much greater than that of the bonds that hold the molecule together. Ionization by electrons is a highly energetic or 'hard' process that may lead to extensive fragmentation that leaves very little or no trace of a molecular ion. Because molecular mass and

structure are not easily determined in the absence of a molecular ion, lower energy or 'soft' ionization techniques have been developed based on chemical and desorption ionization processes.

### Chemical Ionization

Chemical ionization (CI) source is very similar to the EI source but the beam of electrons is used to create a plasma of ionized reagent gas (e.g., isobutane, methane, ammonia).

Transfer of a proton to a sample molecule  $M$ , from an ionized reagent gas such as methane in the form of  $\text{CH}_5^+$ , yields the  $[M + H]^+$  positive ion. This process is less energetic than EI and generally produces less fragmentation. The fragmentation patterns are not necessarily the same as those of molecular ions,  $M^{+\bullet}$ .

Negative ions can also be produced under CI conditions. Transfer of a proton from  $M$  to reagent gas or ions can leave  $[M - H]^-$ , a negatively charged sample ion. Addition of an electron to  $M$ , a process facilitated by collisionally moderating the energy of electrons generated in the source, can yield an intense  $M^-$  ion. Such ions are often the only ion generated and can be used to detect species with great sensitivity.

### Desorption Ionization

Samples may be desorbed and ionized by an impact process that involves bombardment of the sample with high-velocity atoms, ions, fission fragments, or photons of relatively high energy. The impact deposits energy into the sample, either directly or via a matrix, and leads to both sample molecule transfer into the gas phase and ionization.

Field desorption (FD) is perhaps the simplest technique, the sample is coated as a thin film onto a special filament placed within a very high intensity electric field. Ions created by field-induced removal of an electron from the molecule are extracted into the mass spectrometer. Field ionization (FI) is the equivalent process whereby gas-phase molecules are ionized by a high electric potential. These techniques are sometimes applied to relatively large, polymeric molecules but are not commonplace.

### Fast Atom Bombardment/Liquid SIMS

The techniques of fast-atom bombardment (FAB)/liquid secondary ionization (LSIMS), developed in the early 1980s, revolutionized the range of compounds amenable to analysis by MS and opened up the field to many areas of biomedical research. Although now considered insensitive by comparison with more recently introduced ionization modes, FAB still has a role as a rapid, reliable, and robust

technique for samples where quantity and purity are not a problem. The sample is first dissolved in a liquid matrix. This is typically a viscous, low vapor pressure liquid. A few microliters of this liquid are placed on a small metal target at the end of a probe that is inserted into the mass spectrometer. The liquid surface is then bombarded with a beam of high kinetic energy atoms (xenon) or ions (cesium). Molecules sputtered from the surface enter the gas phase and ionize, either by protonation, deprotonation, or adduction. The resulting ions tend to be stable and exhibit little fragmentation.

### Matrix-Assisted Laser Desorption Ionization

Unlike FAB/LSIMS, matrix-assisted laser desorption ionization (MALDI) uses a crystalline, rather than liquid, matrix, and a beam of photons, rather than atoms or ions. The net result is a dramatic increase in both sensitivity and mass range of compounds that may be analyzed. The sample is dissolved in a matrix and is allowed to crystallize on a stainless-steel target. The target is then inserted into the mass spectrometer and the surface bombarded with a pulsed laser beam. Molecules are desorbed from the surface and ionize, usually by protonation or deprotonation. Any fragment or multiply charged ions are generally of low abundance in this ionization mode. The pulsed nature of the laser excitation renders this technique compatible with TOF, and the combined technique enjoys an almost limitless mass range.

### Atmospheric Pressure Ionization Techniques

Atmospheric pressure ionization (API) techniques encompass a range of techniques in which ionization occurs external to the mass spectrometer vacuum. Ionization can be achieved by a variety of methods, including photoionization, corona discharge at the tip of a needle, or by the use of radioisotopes such as  $^{63}\text{Ni}$ .

Atmospheric pressure chemical ionization (APCI) is a simple and robust technique routinely used to interface the eluent from a high-performance liquid chromatography (HPLC) to a mass spectrometer. The liquid stream passes through a heated nebulizer into a corona discharge region. Analyte molecules are ionized and extracted into the mass analyzer.

### Electrospray

Electrospray (ESI) is another example of an API technique.

The sample is dissolved in a mobile phase and pumped through a fine stainless-steel capillary maintained at high potential. This creates an electrostatic spray of multiply charged droplets containing the

sample. At higher solvent flow rates, heat and drying gas may be needed to increase the rate of droplet evaporation. This technique is sometimes referred to as pneumatically assisted ESI or Ionspray.

After desolvation and subsequent charge concentration, gas-phase ions are produced and propelled toward the high vacuum mass analyzer. ESI is considered to be one of the 'softest' ionization techniques available, i.e., little energy is transferred to the molecule other than that required for ionization. Thus, protonated, deprotonated, or cationized molecules that undergo very little fragmentation are generated, even from highly polar, thermally labile molecules.

ESI can impart many charges ( $z$ ), usually in the form of protons, to amenable large molecules such as proteins, and thus compounds with molecular masses in the tens of thousands can be analyzed with mass spectrometers with  $m/z$  ranges of a few thousand. Molecular mass can often be determined to a precision in the order of one part in 10 000 or better. ESI is particularly compatible with liquid separation methods and has become a widely used method in biological and pharmaceutical analysis, where identification is achieved through deconvolution of the envelope of peaks formed with multiple charge states.

### Choice of Ionization Technique

EI and CI are generally the techniques of choice for small ( $<800$  Da), volatile, thermally stable compounds.

CI tends to give molecular weight information and EI, with the greater fragmentation, provides structural information.

FAB/LSIMS is useful for larger ( $\leq 5000$  Da) involatile, polar, thermally unstable molecules, such as peptides, small proteins, and other biopolymers. However, this technique has now largely been superseded by ESI and MALDI.

MALDI is suitable for similar compounds to those amenable to FAB, but affords much greater sensitivity. Biopolymers with molecular weights above 300 000 Da have been successfully analyzed.

ESI is suitable for similar compounds to MALDI, with possibly a slightly reduced sensitivity and mass range. The tendency to produce multiply charged ions brings the mass-to-charge ratios of high molecular weight proteins well within the range of inexpensive mass spectrometers. This has fuelled an explosion in biochemical applications of MS and has spawned the developing fields of proteomics, genomics, and metabonomics.

ESI is frequently interfaced with chromatographic techniques such as HPLC, capillary zone electrophoresis (CZE), and capillary electrochromatography (CEC).

## Sample Introduction Techniques

### Probe Inlets

A direct insertion probe may be used for reasonably pure volatile solids. The sample is loaded into a quartz tube on the tip of a rod that is inserted into the evacuated source region. The sample is then evaporated or sublimed into the gas phase, usually by heating. The gaseous molecules are then ionized (often with accompanying fragmentation) and the ions are mass analyzed. In some techniques, volatilization and ionization occur at the same time.

### Septum Inlets

Heated reservoir septum inlets may be used for pure gases or volatile liquids, comprising a heated reservoir with a small restriction 'bleed' into the ion source. The sample is injected into the reservoir through a septum. This method is commonly used to introduce reference materials for calibration.

### Chromatographic Techniques

To obtain the mass spectrum of a single constituent of a mixture, the individual components often need to be separated prior to analysis. Separation is necessary for unambiguous identification because two compounds present in the source region simultaneously create a mixed spectrum and even simple compounds can generate many fragment ions. The historical combination of GC and MS (GC-MS) allows compounds in the vapor phase to enter the mass spectrometer so that the components of mixtures can be detected and analyzed sequentially.

The challenge in interfacing a mass spectrometer to a separation system like a gas or liquid chromatograph is maintaining the required vacuum in the mass spectrometer while introducing flow from the chromatograph. Interfaces that restrict or reduce the gas flow into the mass spectrometer (e.g., flow splitters or devices that differentially remove carrier gas from the GC effluent) initially made the combination of GC and MS an extremely widely used technique. The low gas flows typical of capillary GC now permit direct connection to mass spectrometers.

More recently, liquid chromatography (LC), supercritical fluid chromatography (SFC), and CZE devices connected to mass spectrometers have been used to separate components of complex mixtures prior to mass analysis. When vaporized, the solvent from an LC represents a volume of 100–1000 times greater than that of a carrier gas used in GC. Interfaces developed commercially have solved the problem of eliminating this gas load by using combinations of heating and pumping, sometimes with

the assistance of a drying gas stream. The inlets for higher flow rates (as in analytical LC) employed in LC/MS systems in routine use are primarily APCI and ESI.

Particle beam interfaces, thermospray, and 'dynamic FAB' have also been used as LC continuous-flow injection techniques, but these have largely been superseded.

For GC-MS, LC-MS, or other combinations, the data consist of a series of mass spectra acquired sequentially in time. To generate this information, the mass spectrometer scans the mass range repetitively during the chromatographic run. The intensities of all the ions in each spectrum can be summed, and this sum plotted as a function of chromatographic retention time to give a total ion chromatogram (TIC) whose appearance is similar to the output of a conventional chromatographic detector. Each peak in the TIC represents an eluting compound that can be identified by interpretation of the mass spectra recorded for the peak. The intensity at a single mass-to-charge ratio over the course of a chromatographic run can be displayed to yield a selected ion current profile or mass chromatogram. This technique can be used to find components of interest in a complex mixture without having to examine each individual mass spectrum.

## Mass Spectrometric Techniques

### Selected Ion Monitoring

SIM is frequently used for the quantitative determination of specific analytes by MS, usually in combination with a chromatographic separation. The mass spectrometer is used to monitor a limited number of ions characteristic of target compounds, rather than to acquire a complete spectrum. The effect is that the instrument spends a greater time recording ions from the analytes of interest with a resulting increase in both sensitivity and selectivity. This is a very sensitive technique and for some compounds it is possible to detect at the femtogram ( $10^{-15}$  g) level.

### Tandem or Multistage Mass Spectrometry (MS/MS, MS<sup>n</sup>)

Tandem MS is used to provide more information than can be afforded by a single mass spectrometer and is widely used for screening complex matrices such as blood and urine. Analysis is achieved, in effect, by performing two stages of SIM. The first mass spectrometer is set to transmit the 'precursor' ion of interest into a region where fragmentation occurs. One of the 'product' ions is monitored by a second mass spectrometer. Selection of an appropriate internal

standard and switching between the gas phase transitions can lead to very high specificity. This technique is known as selected reaction monitoring (SRM), and is frequently used for quantification. Fragmentation is usually achieved in a collision cell pressurized with an inert gas such as argon. Collision of ions with atoms in the cell produces fragments by a process known as collision induced dissociation (CID). Other approaches have been used to cause fragmentation, such as lasers, electron beams, and surface collisions.

In cases where 'soft' ionization techniques are used, the molecular weight of the sample may be observed but the lack of in-source fragmentation means that little structural information is available. A product ion mass spectrum acquired with a tandem mass spectrometer can yield this structurally significant information.

In the technique of precursor ion scanning the second mass spectrometer is set statically to transmit product ions of only one selected mass-to-charge ratio. This mass is monitored continuously whilst the first mass spectrometer is scanned. A signal will be detected only when a precursor ion fragments to form the product ion that is monitored. This technique is often used to screen for compounds of related structure, such as the metabolites of a known drug.

Another tandem screening method is known as constant neutral loss scanning. Here, both mass spectrometers are scanned simultaneously but are offset corresponding to the difference between precursor and product ion masses. A signal only appears when a precursor ion yields a product ion with the mass difference selected. This technique can be used to screen for compounds that contain a specific structural feature that yields a common fragmentation process.

Tandem MS can be performed using sector, quadrupole, and TOF instruments. However, each stage of mass analysis requires a separate mass analyzer. Different mass analyzers are often combined to form tandem instruments for specific applications, e.g., Q-TOF.

Ion trap or ICR mass spectrometers permit MS/MS product ion experiments to be conducted sequentially in time within a single mass analyzer. A number of sequential experiments, termed MS<sup>n</sup>, may be performed.

Modern TOF mass spectrometers incorporate a reflectron unit and the facility to analyze what are known as postsource decay ions. The spectra produced are similar to product ion spectra and can be enhanced by the inclusion of a collision cell.

### Stable Isotope Ratio Mass Spectrometry

Although often presumed to be constant, natural isotope abundance ratios show significant and

characteristic variations when measured very precisely. In stable isotope ratio mass spectrometry (IRMS), element isotope ratios are determined very accurately and precisely. Typically, single focusing magnetic sector mass spectrometers with fixed multiple detectors (one per isotopomer) are used. Complex compounds are reduced to simple molecules prior to measurement, for example, organic compounds are combusted to CO<sub>2</sub>, H<sub>2</sub>O, and N<sub>2</sub>. Isotope ratio measurements are useful in a wide range of applications, for example, metabolic studies using isotopically enriched elements as tracers; climate studies using measurements of temperature-dependent oxygen and carbon isotope ratios in foraminifera; rock age dating using radiogenic isotopes of elements such as lead, neodymium, or strontium; and source determinations using carbon isotope ratios (for example, to discriminate between naturally occurring substances and petroleum-based synthetic materials).

### Pyrolysis Mass Spectrometry

Pyrolysis is the thermal degradation of complex material in an inert atmosphere or a vacuum. Molecules cleave into smaller, volatile fragments called pyrolysate. In pyrolysis MS (PyMS), the pyrolysate is directly analyzed by MS to produce a chemical profile or fingerprint of the complex material analyzed. The development of PyMS was largely driven by its applicability to the characterization of microorganisms and has now largely been supplanted by the application of MALDI in this field. In contrast, pyrolysis GC/MS (Py-GC/MS) still finds numerous applications in the analysis of complex synthetic and biological polymers.

### Elemental Mass Spectrometry

Elemental MS is applied mostly to inorganic materials, to determine the elemental composition of a sample rather than the structural identities of its

chemical constituents. Elemental MS provides quantitative information about the concentrations of those elements. The decomposition of the sample into its constituent atoms and ionization of those atoms occurs in a specially designed source. The ion source used in elemental MS is ordinarily an atmospheric-pressure discharge such as inductively coupled plasma (ICP) or a moderate-power device such as glow discharge (GD). The resulting atomic-ion beam is then separated by a mass analyzer and the signal used to determine the sample composition. With an ICP employed as an ion source, solution detection limits down to the parts per trillion level are possible in favorable cases, while with the glow-discharge source, solid metal samples can be analyzed directly and their elemental composition determined over a million-fold range of concentrations. Isotopic information is readily available.

### Introduction

The mass spectrometer is an instrument capable of producing a beam of ions from a sample under

investigation, separating these ions according to their mass-to-charge ratio and recording the relative abundances of the separated ion species as a mass spectrum. Many types of mass spectrometers have been developed to fulfill the above definition. The widely differing nature and physical state of sample materials has resulted in a variety of techniques for sampling, ionization, ion storage, mass separation, and ion recording. This article on the basic principles of mass spectrometry (MS) will cover the historical

development of the instrumentation and introduce the topics of ionization methods and fragmentation processes before concluding with a brief summary of the approach to interpreting data.

## Instrumental Development

The origins of MS are to be found in studies on the deflection of charged particles in magnetic fields by some eminent nineteenth century experimentalists. The theory of this effect was developed by several researchers with the Nobel Laureates JJ Thompson, KF Braun, and W Wren being the most prominent. The first spectrometer exhibiting velocity focusing was built by FW Aston in 1919. This machine (the mass spectrograph) recorded the separated ion beams on a photographic plate and became associated with the accurate determination of mass. At the same time, AJ Dempster designed a 180° magnetic deflection machine (the mass spectrometer) employing directional focusing and electrical detection of the ion beam. The first spectrometer employing directional and velocity focusing (double focusing) in the same instrument was demonstrated in 1937 (J Mattauch and R Herzog) and the concept was repeated in the Nier-Johnson machine of 1953, which employed an alternative ion path geometry. It is this latter design that has been developed into the modern chemical analysis spectrometer incorporating high-resolution accurate mass determination. The availability of commercial high-performance chemical analysis mass spectrometers generated a demand for ionization techniques capable of producing positive and negative molecular ions from compounds that provide fragment ion spectra (i.e., no molecular ions) under electron bombardment. The techniques developed include photoionization (PI), fast atom or ion bombardment (FAB), field desorption (FD) or field ionization (FI), plasma desorption, matrix-assisted laser desorption ionization (MALDI), chemical ionization (CI), atmospheric pressure chemical ionization (APCI), and electrospray (ESP). The introduction of samples to the spectrometer, conventionally achieved by gaseous leak for gas and volatile liquid samples and by direct insertion probe for solids and involatile liquids, was expanded by the successful interfacing of a range of chromatographic techniques to the spectrometer. The availability of direct mixture separation via gas, liquid, supercritical, and thin-layer chromatography has removed the necessity for difficult and time-consuming chemical or physical separation outside the spectrometer. At present no universal interface is available for all chromatograph-spectrometer combinations, although the eluent from capillary gas chromatography

can be directly introduced into the mass spectrometer ion source as can the eluent from high-performance liquid chromatography when using APCI or ESP ionization. The two-dimensional separation supplied by chromatography-mass spectrometry is also intrinsic to the linked MS-MS technique. In this approach, normally preceded by soft ionization, the pseudomolecular ion derived from an unknown compound is selected from a mixture of ions by a magnetic field ( $B$ ) combined with an electric sector field ( $E$ ) in a double focusing instrument, or quadrupole field ( $Q$ ), and is passed through a cell containing a high pressure of collision gas, normally helium or argon. In this cell collision-activated decomposition to characteristic daughter (fragment) ions occurs. These ions have the same velocity but different mass and therefore different energies, and thus may be separated by a variety of analyzer types mounted after the collision cell. This area has seen much recent growth and most possible combinations of mass analyzers have been investigated. The conventional mass separation of ion beams by magnetic and electrostatic fields has been extended by the introduction of radio frequency (RF) fields for mass separation in quadrupole mass spectrometers. This technique has itself been further developed in the QUISTOR (quadrupole ion storage) or ion trap. Another technique employing the trapping principle is ion cyclotron resonance Fourier transform mass spectrometry, one of the key features of which is the simultaneous detection of all ions. Coupled with pulsed laser ionization this has proved useful in the analysis of sensitive high-mass molecules of biological origin and is capable of unrivaled resolution at lower mass. Time-of-flight (TOF) spectrometers in which ion separation is achieved in time rather than in space are also particularly amenable to pulsed ionization techniques. Current TOF machines do not need a magnetic focusing field for mass separation and are therefore linear in design and light in weight and have consequently found application in space research. When used with an RF biasing field they also find employment in isotopic ratio measurements or the collection of single isotopes in the nuclear industry. Due to the potentially unlimited mass range parent ions of heavy biological molecules (up to 1 000 000 Da) can also be detected and MALDI-TOF-MS of biological species has become a very important technique. The potentially unlimited mass range of the TOF spectrometer is to some extent offset by the relatively high (up to 20 000) but still limited resolution available from modern instruments. The detection of the separated ion beam on photographic plates is still practiced in spark source spectrometers for the analysis of, among others, high-melting point inorganic samples. This is a

time-consuming process requiring the production of photoplates of standard materials for quantitative work and a significant time period is necessary for plate development. Electrical detection, originally achieved with the Faraday cage or hollow cylinder and still used for precision isotope studies, has been replaced by the high-gain electron multiplier or photomultiplier. Both the discrete dynode and continuous dynode multiplier have successfully lowered the minimum detectable ion current to the  $10^{-18}$  A level, resulting in typical minimum detection levels in the picomole range for many organic compounds. Channel electron multiplier/photodiode arrays enable the counting of single ions and the simultaneous detection of ions in a broad mass range leaving the separation field.

Almost all the major advances evident in the present generation of mass spectrometers can be traced to concurrent advances in semiconductor and data processing technology. For the first 50 years of spectrometer development, all control and handling was achieved by manual means. Offline data handling of the digitized ion current was the first step toward computer control, followed by online real-time processing. Control of the mass separation region then became available producing the capability for single ion monitoring, MS-MS, and linked scan functions. Today, the complete spectrometer comes under precise digital control and commercial 'user-friendly' machines are available for a variety of applications requiring a minimum knowledge of MS by the user.

Computer library searching of spectral databases is routinely available. The database is usually a component part of the spectrometer although the search may be undertaken remotely. Several attempts have been made to develop artificial intelligence systems for direct spectral interpretation, but to date these have met with limited success. Advances in computer control have allowed multiexperiment analysis in which the spectrometer will follow a set of experiments sequentially while automatically adjusting operating parameters as directed by the results of the preceding experiment. Further advances in this area are anticipated.

## Ionization Processes

### Electron Bombardment

The first step in the production of a spectrum of ions from a gaseous molecular sample is the removal or addition of one or more electrons from the molecule, resulting in the acquisition of charge with negligible change in mass.

**Positive ion formation** The formation of a positive ion is normally expressed as

where  $M^{+\bullet}$  is known as the molecular ion. The molecular ion is the heaviest ion in the spectrum that can be produced by unimolecular reaction and is of considerable importance as it provides the relative molecular mass of the sample.

The probability of a bombarding electron producing a positive ion is a function of the electron's kinetic energy and a plot of this probability as a function of energy constitutes an ionization efficiency curve. Such curves show that a threshold energy exists (the appearance potential) below which ionization cannot occur. The energy at which the singly charged molecular ion appears is referred to as the first ionization potential. The time taken for interaction between a bombarding and orbital electron is  $\sim 2.4 \times 10^{-16}$  s, in which time the ionization must have occurred. The fastest molecular vibration is C-H stretching, with a period of  $\sim 10^{-14}$  s. Hence, the atoms may be considered to be at rest during the ionization process and thus satisfy the Frank-Condon principle (Figure 1).

The minimum energy required to form molecular ions by electron bombardment is known as the 'vertical' ionization potential ( $IP_v$ ) and may exceed the minimum energy necessary to produce molecular ions in the ground state (the 'adiabatic' ionization potential  $IP_a$ ). The stability of the molecular ion determines its abundance relative to ions that are formed by its fragmentation. The time elapsing between ionization

**Figure 1** Frank-Condon diagram showing (A) vertical, and (B) adiabatic transitions. Appearance potential =  $IP_a + E_a$ .

and detection of any ion is  $\sim 10^{-5}$  s and if a molecular ion fragments in significantly less than this time it will not appear in the recorded spectrum. The rate of fragmentation is a function of the excess energy of the ion on formation; the number of molecular ions reaching the collector will therefore increase as the ionizing energy is reduced toward the ionization potential. The stability of the molecular ion will also decrease with increasing molecular size across a homologous series as a greater number of fragmentation pathways are available to larger molecules.

Addition of a stabilizing entity into a chain will dramatically change molecular ion intensity. The aromatic nucleus and other conjugate systems are particularly notable in this respect as the radical site may be dispersed by conjugation over an extended part of the ion. Stabilization is also found in compounds containing unsaturated functional groups such as carbonyl, nitro, nitrite, and sulfonyl.

**Negative ion formation** During the ionization process described above, in addition to the production of positive ions, a small number of molecules undergo addition of one or more electrons to form negative ions. At the operating ionizing energy of the analytical mass spectrometer (60–100 eV), the sensitivity of negative ion formation is several orders of magnitude less than that for positive ion production. If a neutral molecule is bombarded with electrons of increasing energy a sharp peak in ion production is observed between 0 and 10 eV. The energy at which this peak appears is determined by the electron affinity of the molecule and its narrow nature shows electron attachment to be a resonance process. An interest in analytical negative ion spectra developed when production of a sufficiently high flux of low-energy electrons became readily available. This was achieved by employing a high pressure of reagent gas as an energy moderator for energetic electrons.

Negative ions are produced either directly by electron capture or by ion–molecule reactions with anionic species.

Three methods of direct electron capture may occur:

1. associative resonance capture ( $AB + e^- \rightarrow AB^{\cdot-}$ );
2. dissociative resonance capture ( $AB + e^- \rightarrow A^- + B^{\cdot}$ ); and
3. ion pair production ( $AB + e^- \rightarrow A^+ + B^- + e^-$ ).

As the electron affinities of most organic materials do not exceed 2.5 eV, the reagent gas not only acts as a means of producing thermal electrons but also provides collisional stabilization of the anions formed.

## Chemical Ionization

The process of chemical ionization in the mass spectrometer bears several similarities to the production of negative ions described above. The characteristic ionization of the sample is achieved by ionic reaction and the technique also requires a high pressure (up to 1 Torr) of reagent gas in the source. The partial pressure of sample to reagent gas does not normally exceed 0.01%. The energy transfer in the CI process is low compared to that for electron impact (EI) ionization and in general does not exceed 5 eV. The technique is therefore referred to as ‘soft ionization’ and is capable of producing extremely stable pseudomolecular ions (often protonated) and little fragmentation. Compounds that are thermally labile or unstable to EI ionization readily produce molecular ion data under CI. By varying the nature of the reagent gas to provide more energetic ionization, fragmentation data may also be obtained. The reactions between sample molecules and positively charged reagent ions fall broadly into four groups: proton transfer, charge exchange, electrophilic addition, and anion abstraction.

**Proton transfer** The general reaction is

It should be noted that the proton affinity (PA) for the addition

is expressed as  $-\Delta H$  for that reaction and that for the general proton exchange reaction shown above

that is, the reaction is exothermic.

Hydrogen is the most exothermic of all protonating agents ( $PA = 423 \text{ kJ mol}^{-1}$ ), followed by methane ( $PA = 536 \text{ kJ mol}^{-1}$ ). Both of these reagents, however, tend to produce excessive fragmentation. If molecular ion information is required, isobutane or ammonia ( $PA = 810$  and  $847 \text{ kJ mol}^{-1}$ , respectively) provide the necessary ‘soft’ ionization.

## Other Ionization Processes

A variety of other techniques based on the reaction of ionizing agents with sample molecules are readily available to the mass spectrometrists. FAB and secondary ion mass spectrometry (SIMS) are used to analyze nonvolatile solids and use respectively energetic atoms and ions to achieve sputtering of the sample including ionization. Laser and PI and FD/FI are also well-established techniques. Inorganic materials may be ionized by arc discharge,

inductively coupled plasma (ICP) or SIMS, or glow discharge. Perhaps two of the most important techniques today are ESP ionization and MALDI. Both these techniques are heavily utilized in the identification of proteins and other biological polymers at high molecular mass (up to 1 000 000 Da). These techniques have increased in importance as MS has increased its role in biomedical sciences and both are now the basis for the use of MS in studies of the total cellular protein complement (proteomics). A detailed theoretical discussion of the ionization processes involved in these techniques is beyond the scope of this introductory article.

## Fragmentation

The electron bombardment ionization of a molecule as described above produces an excited molecular ion, which, in attempting to gain stability, may decompose in a number of different ways by unimolecular reaction to fragment ions or neutrals. The relative abundance of the molecular ion is determined by its ability to resist decomposition, but the stability of fragment ions is dependent on the relative rates of reaction that form and destroy the ion.

The factors that play a role in determining the fragment ions derived from a particular molecular ion are:

1. the relative stabilities of the bonds in the decomposing ion,
2. the relative stabilities of the ions and neutrals formed by various pathways, and
3. the relative probabilities of decomposition pathways involving cleavage of bonds in transient cyclic intermediates.

The reactivity of a molecular bond is normally mirrored by that bond's tendency to break down under electron impact. For example, in  $\text{CH}_2\text{Cl}-\text{CH}(\text{CH}_3)_2$ , the 1–2 bond is the most chemically labile due to the polarizability of the isopropyl group and the inductive effect of the halogen. In an analogous way, the majority of the fragment ions in the mass spectrum of this compound are produced by 1–2 cleavage. The chemical lability of allylic and benzylic bonds is also closely mirrored by their electron impact-induced cleavage. The simplest indicator of a fragment's stability is its odd- or even-electron nature with even-electron species, whether ion or neutral, showing greatly enhanced stability and therefore exerting most influence on subsequent decompositions. Simple homolytic cleavage of an odd-electron molecular ion normally provides an

even-electron ion and odd-electron radical. To produce an odd-electron ion, it is necessary for the molecular ion to undergo energetically less-favored multiple-bond cleavage or rearrangement. The positive charge on the product ion is normally located in the fragment with the lowest ionization potential (Simpson's rule). Because even-electron species containing only paired electrons tend to be more stable than odd electron species, fragmentations producing such products tend to predominate.

Fragment ions may also arise directly by the pair-production process without passing through a molecular ion stage:

Halogen compounds that can provide stable atomic halogen negative ions are frequently found to fragment in this way.

The fragmentation of an ion often involves a transfer or rearrangement of atoms between products accompanied by the breaking of one bond and the formation of another, and may be represented by

This rearrangement process often involves hydrogen but species as diverse as fluorine, methyl, ethyl, methoxy, and phenyl or hydroxy may be involved, leading to products of enhanced stability. For a rearrangement reaction to produce observable quantities of product, the unfavorable entropy of the reaction must be more than balanced by particularly favorable activation energy.

When the fragmenting ion contains a heteroatom, abundant rearrangement ions are often formed in the spectrum via a transition state in which the charge is localized on the heteroatom. The McLafferty rearrangement of ketones may be used to illustrate this process:

The product ion has lost one of the oxygen lone pair electrons in the ionization process and  $\text{O}^+$  is therefore trivalent. A similar valency increase can occur in rearrangements involving nitrogen as shown in the formation of the ammonium  $\text{R} + \text{NH}_3$  from secondary amines. The McLafferty rearrangement is the most generally applicable rearrangement process observed in the production of mass spectral fragmentations and requires the presence of a multiple bond and a  $\gamma$ -hydrogen if it is to occur. Aldehydes, olefins,

amides, nitrites, esters, substituted aromatics, phosphates and sulfites have all been shown to rearrange by a McLafferty mechanism.

Another well-known process producing abundant rearrangement ions in the mass spectrum is the retro-Diels–Alder reaction of cyclic olefins. The simplest example of this is shown by cyclohexene:

Identification of a molecule from ions produced by this type of rearrangement can be obscured by the migration of hydrogen, and thus the site of the double bond in the molecule before fragmentation may be uncertain. The cyclic olefin 1,2-dimethylcyclohexene is found to produce a base peak at  $m/z$  68, suggesting that the compound is the 1,3-isomer. Production of this peak must be preceded by isomerization of the double bond:

## Interpretation

As with most other spectroscopic techniques, interpretation of the data relies on a combination of an understanding of the fundamental processes going on, the application of logical reasoning, and the use of intuition. There are no hard and fast rules over the best approach; however, certain things should be looked for and the procedure outlined below should yield substantial information:

1. The first and probably most important step in the identification of a compound from its mass spectrum is identification of the molecular ion.

- Note odd or even mass – remember the nitrogen rule.
- Note the isotope pattern – halogens, etc.
- Note the intensity – strong  $M^{+\bullet}$  may mean aromatic.
- If an accurate mass is available, calculate the molecular formula.
- Consider degree of unsaturation, i.e., rings plus double bonds.

2. Identify prominent odd electron ( $OE^{+\bullet}$ ) and even electron ( $EE^+$ ) ions.

- Calculate possible neutral losses and relate to structural units.
- Consider rearrangements.

3. Identify metastable peaks if present.

- Establish connectivity relationships.
- Consider rearrangements.

4. Identify major low mass peaks that relate to neutral losses and structural units.

5. Look for characteristic ion series that identify the compound class, some examples are given below:

27, 41, 55, 69, etc.	Alkenyl	$C_nH_{2n-1}$
15, 29, 43, 57, 71, etc.	Alkyl	$C_nH_{2n+1}$
29, 43, 57, 71, etc.	Aldehydes/ ketones	$C_nH_{2n-1}O$
30, 44, 58, 72, etc.	Amines	$C_nH_{2n+2}N$
39, 50–52, 63–65, 75–78	Aromatics	

All the above procedure may assume less significance if computer-aided library searching is available. The library may not contain an entry for the sample under examination, but will always provide a best-match spectrum. Close scrutiny of the 'goodness of fit' of the library and acquired data is therefore essential if the possibility of an erroneous match is to be avoided.

Many combinations of the basic techniques are known, the exact specification being determined by the function to be addressed. Thus, organic materials, often thermally sensitive and labile, require less energetic (softer) ionization (e.g., CI or laser desorption) than high-melting-point inorganic materials (e.g., ICP or arc discharge ionization). Molecular ion and fragmentation data (from EI ionization) may be required for the identification of unknown molecular materials, while monitoring of a single ion, selected from the complete spectrum, may be all that is required for the identification of a trace impurity. Measurement of isotope ratios in molecular or atomic spectra may be used to identify or quantify polyisotopic species (e.g.,  $^{12}C/^{13}C$  ratio, halogen identification,  $^{32}S/^{34}S$  ratio, and medical tracer identification). The physical state of sample material will determine the method adopted for introduction into the spectrometer, differing techniques being available for gaseous, liquid, and solid samples. Several methods are also available for the separation of sample mixtures before ionization, interfaces being available for gas chromatography, liquid chromatography, supercritical fluid chromatography, capillary electrophoresis, and thin-layer chromatography.

The applications of mass MS are extensive and may be found in many spheres of scientific investigation. The range includes purely physical measurements such as appearance potentials, kinetic studies on ultra-short-lived ionic species, isotopic ratio measurements for dating or health studies, ion structure investigations, and a vast array of qualitative and quantitative analytical procedures employed in chemistry, biochemistry, medicine, nuclear science, and semiconductor engineering.

## Introduction

In order to obtain the mass spectrum of a compound, it must first be ionized. Early methods involved thermal evaporation of samples into the ion source of the mass spectrometer where they were ionized by electron beam bombardment or chemical reactions. Thermal instability, where present, was frequently overcome by derivatization. For large and involatile molecules, desorption techniques using high electric fields or bombardment with fission fragments, fast atoms, fast ions, or laser beams were later developed. The newest techniques, developed in the late 1980s, involve laser ionization of samples imbedded in a solid matrix and evaporation of solutions by electrospray. Both of these techniques are able to ionize large molecules such as proteins with masses of up to several hundred kilodaltons. This article describes these techniques in more detail and indicates the type of mass spectrometer that is suitable for analysis of the types of ion that they produce.

## Ionization Methods

### Electron Impact

In the electron impact (EI) method, the ion source consists of a small (~10 mm across) heated chamber located within the vacuum system (Figure 1). A beam of electrons, generated from a heated tungsten or rhenium filament, is sent through the chamber to a second electrode, known as the trap. The voltage difference between the filament and trap governs the energy of the electrons and is usually set at some value above the ionization potential of the sample molecules, typically 70 eV. Small permanent magnets are positioned in line with the electron beam to cause the electrons to execute a spiral path in order to increase the path length. Sample molecules are evaporated either outside the ion source or within it from the sample deposited on a heated probe and, when bombarded with the electron beam, absorb energy and ionize by release of an electron:

The resulting ion is termed an odd-electron molecular ion and is written in the form  $M^{+\bullet}$ . The ionization efficiency is low with only about 1 in  $10^3$  sample molecules producing ions. However, the high

The applications of mass MS are extensive and may be found in many spheres of scientific investigation. The range includes purely physical measurements such as appearance potentials, kinetic studies on ultra-short-lived ionic species, isotopic ratio measurements for dating or health studies, ion structure investigations, and a vast array of qualitative and quantitative analytical procedures employed in chemistry, biochemistry, medicine, nuclear science, and semiconductor engineering.

## Introduction

In order to obtain the mass spectrum of a compound, it must first be ionized. Early methods involved thermal evaporation of samples into the ion source of the mass spectrometer where they were ionized by electron beam bombardment or chemical reactions. Thermal instability, where present, was frequently overcome by derivatization. For large and involatile molecules, desorption techniques using high electric fields or bombardment with fission fragments, fast atoms, fast ions, or laser beams were later developed. The newest techniques, developed in the late 1980s, involve laser ionization of samples imbedded in a solid matrix and evaporation of solutions by electrospray. Both of these techniques are able to ionize large molecules such as proteins with masses of up to several hundred kilodaltons. This article describes these techniques in more detail and indicates the type of mass spectrometer that is suitable for analysis of the types of ion that they produce.

## Ionization Methods

### Electron Impact

In the electron impact (EI) method, the ion source consists of a small (~10 mm across) heated chamber located within the vacuum system (Figure 1). A beam of electrons, generated from a heated tungsten or rhenium filament, is sent through the chamber to a second electrode, known as the trap. The voltage difference between the filament and trap governs the energy of the electrons and is usually set at some value above the ionization potential of the sample molecules, typically 70 eV. Small permanent magnets are positioned in line with the electron beam to cause the electrons to execute a spiral path in order to increase the path length. Sample molecules are evaporated either outside the ion source or within it from the sample deposited on a heated probe and, when bombarded with the electron beam, absorb energy and ionize by release of an electron:

The resulting ion is termed an odd-electron molecular ion and is written in the form  $M^{+\bullet}$ . The ionization efficiency is low with only about 1 in  $10^3$  sample molecules producing ions. However, the high

sensitivity of the mass spectrometer is more than adequate to produce a strong spectrum. The extent to which a molecule ionizes is related to the structure; molecules containing heteroatoms with lone pairs of electrons ionize well by loss of one electron from a lone pair, whereas molecules such as saturated hydrocarbons are difficult to ionize as all electrons are involved in sigma bond formation.

Odd-electron ions are generally unstable and decompose, usually by several consecutive and competing reactions within the ion source in an attempt to stabilize the odd electron. Typical fragmentation

pathways include radical elimination to give an even-electron ion [II], neutral molecule elimination to give another odd-electron ion [III], or fragmentation by rearrangement, often involving migrations of hydrogen atoms. Only the ions, not the neutral species, appear in the spectrum:

The resulting array of parent and fragment ions constitutes the mass spectrum of the sample (Figure 2). Such spectra are very reproducible for a given electron beam energy; 70 eV being chosen as a value that produces negligible changes in the spectrum for small changes in electron energy. Many collections of spectra have been published and a vast amount of published material exists on the chemistry of these fragmentation mechanisms; most reactions are unimolecular although some ion-molecule reactions have been reported for selected compounds.

Ions are ejected from the ion source and focused into a beam by a positive potential on a repeller plate positioned at the back of the ion source and a high potential, in the order of 5–10 kV at the front of the source. The beam then enters the analyzer section of the instrument for mass separation to form the spectrum. As the molecules are essentially ionized in the vapor phase, they must be stable at the temperatures needed to vaporize them. Many molecules do not fulfill these requirements but can be stabilized and made more volatile by derivatization. However, even with derivatization and heated ion sources, the technique is only applicable to molecules with masses less than ~1000.

Figure 1 EI ion source.

Figure 2 EI mass spectrum of a fatty acid derivatized as its picolinyl ester.

## Chemical Ionization

**Positive ion chemical ionization (CI)** The instability of odd-electron ions formed by EI frequently results in spectra in which the molecular ion peak, the most important in the spectrum, is absent as none of the ions survive long enough to reach the detector. A solution exists in the form of the CI source. This is constructed in a similar manner to the EI source but has a much smaller exit slit, thus making it much more gas-tight, allowing pressures of 0.1–1 Torr to be achieved. A so-called reagent gas is introduced into the source chamber and ionized by the electron beam. Although a large number of suitable gases have been reported, methane, *iso*-butane, and ammonia are the most common. Once ionized, the gases undergo a series of ion–molecule reactions to form species such as  $\text{CH}_5^+$  (from methane) and  $\text{NH}_4^+$  (from ammonia). These species are allowed to react with the sample molecules, present at partial pressures of  $\sim 0.01\%$  of the reagent gas pressure, with a variety of outcomes. Five common reactions are outlined below:

- (i) Proton transfer, typically from hydrocarbon reagent gases and ammonia

- (ii) Charge exchange from, for example, benzene

- (iii) Electrophilic addition

- (iv) Anion abstraction as with nitric oxide

- (v) Hydride ion extraction

Of these reactions, the formation of  $[\text{M} + \text{H}]^+$  is the most common. Species formed in these reactions by addition or subtraction of atoms are sometimes referred to as pseudomolecular ions as they do not have the same elemental composition as the charged molecule but the term appears to be falling out of favor.

These ionization reactions involve transfer of much less energy to the sample molecules than EI and, consequently, there is much less fragmentation. CI is generally termed a soft ionization technique. In addition, the  $[\text{M} + \text{X}]^+$  or  $[\text{M} - \text{X}]^+$  species do not contain unpaired electrons, i.e., they are even-electron ions. Consequently, they are much more stable than the odd-electron ions and show very little fragmentation (**Figure 3**). EI and CI are, thus, complementary ionization techniques for the same types of volatile molecule and have been combined into a single ion source in a technique termed ACE (alternate CI/EI). Essentially, a CI spectrum of the sample is acquired to produce a strong molecular ion, after which the CI reagent gas is removed and an EI spectrum is acquired to record the fragments. The reagent gas is then pulsed back and the process is repeated. Another variant of the technique is desorption CI in which the sample is introduced as a solid on a probe and subsequently ionized by the reagent gas.

**Negative ion CI** For mainly historical reasons, mass spectrometry is commonly regarded as a positive ion technique. However, many ionization processes produce both positive and negative ions, sometimes favoring the latter. CI is one such technique and, again, several reactions are recognized:

- (i) Electron capture from thermal electrons

- (ii) Proton abstraction

**Figure 3** (Left) EI spectrum of a drug molecule exhibiting no molecular ion. (Right) CI mass spectrum of the same compound with *iso*-butane as the reagent gas. The ion at  $m/z$  57 is from the reagent.

## (iii) Charge exchange

## (iv) Nucleophilic addition from, for example, chlorine produced from methylene dichloride

## (v) Nucleophilic displacement with reagents such as nitrous oxide

Capture of electrons that have been thermalized to 0–2 eV can be a very efficient process with suitable compounds and can, thus, often produce greater sensitivity than EI. Many molecules that are not efficiently ionized by this technique can be derivatized with electron-capturing reagents such as fluorocarbon esters in order to increase their susceptibility. This technique is often used for trace analysis, particularly as the derivatization reaction can be compound specific.

**Field Ionization**

A major problem with the above ionization techniques is that they require volatilization of the sample, usually by heating, and are, thus, only suitable for relatively small molecules. This fact delayed the introduction of mass spectrometry into biochemical areas where many of the potential target molecules such as proteins and nucleic acids could not be ionized. There are now many techniques capable of ionizing these molecules, one of the earliest being field ionization (FI). Ionization is produced by exposing the molecules, in the vapor phase, to a strong electric field produced by a sharp point or edge. This electrode is placed a short distance from a cathode such that a field of  $\sim 10^7$ – $10^8$  V cm $^{-1}$  is generated (Figure 4). This field is sufficient to abstract an electron from many types of compound with little excess energy transfer such that  $M^{+\bullet}$  or, occasionally,  $[M + H]^+$  ions are generated. The odd-electron nature of the  $M^{+\bullet}$  ions usually leads to some fragmentation.

**Figure 4** FI ion source.

**Field Desorption**

In a related technique, field desorption (FD), a strong electric field (typically  $10^7$ – $10^8$  V cm $^{-1}$ ) is again used to extract ions from the compound of interest but, in this case, the sample is placed onto a probe, termed the emitter, usually by evaporation. The emitter is covered with a large number of short whiskers with tip radii in the region of 0.1 nm in order to increase the surface area and enhance the electric field. Although spectra can often be obtained at ambient temperature, heating the probe often increases the ion yield. As the sample is not evaporated prior to ionization, but relies on desorption of the sample molecules, the technique can be used for many large, thermally unstable compounds such as peptides and carbohydrates. Unfortunately, unlike the ionization methods described above, the beam of ions only lasts for a short time giving little scope for experimentation.

The technique is very soft usually with the production of only  $M^{+\bullet}$  ions. Energy transfer to the molecules is in the order of fractions of an electronvolt and, consequently, fragmentation is minimal. Some thermal fragmentation may, however, occur as the result of probe heating. Unfortunately, preparation of the emitters is difficult and labor intensive and ions are produced with a large energy spread such that only instruments such as magnetic sector spectrometers are suitable for analyzing them. The technique now enjoys little but historical interest as it has been replaced by the more convenient methods of fast atom bombardment, laser ionization methods, and electrospray, as discussed next.

**Secondary Ion Mass Spectrometry, Liquid  
Secondary Ion Mass Spectrometry, and  
Fast Atom Bombardment**

The introduction of fast atom bombardment (FAB) in 1981 revolutionized organic mass spectrometry in that it provided an easy and convenient method for ionizing thermally unstable molecules with masses up to  $\sim 10$  kDa. It developed from surface ionization methods in which beams of fast atoms or ions are used to sputter ions from solid surfaces in a technique known as secondary ion mass spectrometry (SIMS). However, although organic molecules can often be ionized directly in a similar manner, the resulting ion beam is too transient to be of any use in the types of mass spectrometer available in the early 1980s (mainly magnetic sector and quadrupole instruments). The difference with FAB is that the sample is dissolved in a high-boiling solvent such as glycerol, known as the matrix, before being placed

on the probe (Figure 5). If the sample is hydrophobic or can be made so by derivatization, e.g., by permethylation, it is repelled by the solvent molecules and forms a layer on the surface of the matrix. This layer is evaporated and ionized by the fast atom beam (5–8 keV), after which, more sample molecules migrate to the matrix surface to maintain the beam. Ion beams can be maintained for 10–15 min. Because it can take time for the surface layer to reform, a modification of the technique, known as pulsed FAB, in which the atom beam is pulsed, has been used to ensure that there is always sample available for ionization and that the atom beam does not ionize predominantly matrix molecules, which would degrade the signal-to-noise ratio. For large molecules, xenon is the preferred gas because of its mass. However, xenon is expensive and a beam of cesium ions is frequently used as a substitute. With ions as the ionizing

beam instead of atoms, the technique is known as liquid secondary ion mass spectrometry (LSIMS).

Ionization of matrix molecules is one of the drawbacks of FAB as it results in spectra with a comparatively high background throughout the mass range with adverse effects on sensitivity. Both positive and negative ions are produced and are mainly of the type  $[M + H]^+$  or  $[M + X]^+$  (depending on the matrix) where X can be moieties such as Na, K, or  $NH_4$  or, in negative ion mode,  $[M - H]^-$ . There is often a considerable amount of fragmentation (Figure 6). Matrices vary, depending on the sample. Glycerol was the first to be used and is often the first choice but others, such as thioglycerol and *m*-nitrobenzyl alcohol, are also popular.

Construction of an FAB ion source is comparatively simple and consists mainly of the sample probe and extraction electrode. The sign of the charge on these electrodes governs whether positive or negative ions are extracted. The fast atom beam is generated by ionizing a noble gas such as argon or, less commonly, xenon, forming a beam from the ions and then removing the charge by passing the beam through a relatively high pressure region. The resulting atoms have sufficient kinetic energy to proceed to the target.

**Continuous flow or dynamic-FAB** As FAB essentially works in the liquid phase, it has been used to ionize molecules infused into the mass spectrometer

**Figure 5** Fast atom bombardment ion source.

**Figure 6** FAB spectrum of the permethyl derivative of a complex carbohydrate.

in solution or as effluents from high-performance liquid chromatography (HPLC) columns. The matrix, in these instances, has reduced viscosity and consists of, for example, water containing 5% glycerol. This solution can be effused directly onto the surface of the probe through a narrow capillary. Related to this method is the technique of frit-FAB in which the solution, usually from an HPLC column, passes through a fine stainless steel frit in order to disperse the liquid.

### Plasma Desorption Mass Spectrometry

Another early desorption technique is that of plasma desorption mass spectrometry (PDMS). The sample is deposited onto a thin aluminum or aluminized polyester foil (0.5–1  $\mu\text{m}$  in thickness) and placed just in front of a californium-252 emitter which is located in a time-of-flight (TOF) mass spectrometer (Figure 7). Californium is an  $\alpha$ -emitter that decays into two highly energetic  $\alpha$ -particles that are expelled in diametrically opposite directions. One of these particles collides with and ionizes the sample while the other hits a collection plate and triggers the timing circuit for the TOF mass spectrometer.

Although largely obsolete, PDMS was initially the only ionization technique capable of analyzing high-mass compounds such as small proteins and polar anionic carbohydrates. Proteins were best examined on foils covered with a layer of nitrocellulose to which the protein adhered and from which contaminants could be removed by washing with water. Following analysis, the residual sample could be recovered from the foil for further experiments. A major disadvantage of the technique was the slow rate of ion production resulting in acquisition times of several hours.

### Thermospray and Plasmaspray

The thermospray ion source was originally developed as a method for introduction of the relatively large volumes of liquid (1–1.5  $\text{ml min}^{-1}$ ) from a

liquid chromatographic system into a mass spectrometer and it was only by accident that the device was found to produce ions. The source consists of a heated capillary of inside diameter  $\sim 100 \mu\text{m}$ , through which the solvent flows into a heated source region, an orthogonally positioned sample cone for transferring ions to the mass spectrometer and a large pump, often with a solvent trap to remove the vapor. A repeller electrode opposite the cone or just downstream (known in this case as the retarder) aids ion transit to the spectrometer (Figure 8). The source may also be provided with a discharge electrode, or filament, to facilitate ionization by stripping electrons from the sample molecules. Under these conditions, the technique is known as plasmaspray.

The temperature of the capillary is adjusted so that  $\sim 95\%$  of the solvent evaporates to provide a nebulizing gas that causes the remaining solvent, which normally contains a volatile buffer such as ammonium acetate, to form small droplets that subsequently evaporate. Ionization is by CI processes, is mild, and produces ions such as  $[\text{M} + \text{H}]^+$  and  $[\text{M} + \text{NH}_4]^+$ . Both positive and negative ions are produced, unlike electrospray in which the capillary carries a high potential (see below). Spontaneous fragmentation by loss of neutral molecules is sometimes seen but the discharge electrode can be used to produce additional ionization when no buffer is present. Ionization is very dependent on the sample and ion source conditions and the technique does not work as well for large compounds such as proteins as it does for smaller molecules such as drugs and drug metabolites, an area in which it has had extensive use. Electrospray has now largely replaced thermospray

Figure 7 Plasma desorption ion source.

Figure 8 Thermospray ion source.

as a means of introducing LC effluents into a mass spectrometer.

### Electrospray Ionization

In the late 1980s, two techniques, electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI), emerged and caused a further revolution in mass spectrometry as each was capable of ionizing extremely large molecules in excess of several mDa. This led to the joint award of the 2002 Nobel prize for chemistry. The electrospray ion source works at atmospheric pressure and consists of a stainless steel or metalized silica capillary held at a high potential, typically  $\sim 3$  kV, and placed a few millimeters from a counter electrode (Figure 9). A solution of the sample flows through the capillary and charged droplets emerge into the ion source where they meet a counter flow of warm nitrogen gas, sometimes known as a curtain gas, to vaporize the solvent. As the droplet diameter decreases, a point is reached where electrostatic repulsion causes the droplet to disintegrate into smaller droplets. The process continues until only ionized sample molecules remain. These are extracted by a sampling cone placed off-axis or at right angles to the solvent flow and introduced into the mass spectrometer. Typical solvents are mixtures of water and either methanol or acetonitrile; pure water or nonpolar organic solvents are less effective. Efficiency can be improved by use of a coaxial nebulizing flow of nitrogen around the spray; a technique known as ion-spray.

The main feature of the electrospray process is that it produces multiple-charged ions. For a typical protein, an average of one charge is added for each kDa in mass. Both positive and negative ions of the type  $[M + nH]^{n+}$ ,  $[M + nX]^{n+}$ , or  $[M - nH]^{n-}$  are produced with a typical spectrum consisting of an array of ions, each differing by one charge state (Figure 10). Although instrumental resolution is not usually sufficient to enable the charge state to be determined directly by observation of the isotopic peak spacing, measurement of the  $m/z$  values of each peak and knowledge that the charge difference between any pair of peaks is one charge enables the mass to be

calculated. As many pairs of peaks are available for measurement, an extremely accurate measurement of the mass can be obtained, usually better than 0.01%; this measurement is made in the background by the instrument's data system and a reconstructed mass spectrum consisting of one peak for each component is produced.

The essential feature of the electrospray spectrum that enables compounds of high mass to be examined is the multiple charging. Typical  $m/z$  values are in the region below  $\sim 5$  kDa and, consequently, typical quadrupole or related instruments can easily analyze the ions with no modification being needed. As the method accepts a flowing solvent, it is ideally coupled to liquid chromatographic columns and has major applications in the field of protein and peptide analysis.

**Nanospray** Nanospray is a variant of electrospray in that the solvent is sprayed from a very fine capillary at flows that can be as low as  $20 \text{ nl min}^{-1}$ . Sensitivity is good and desolvation is enhanced because of the small initial droplet size. Furthermore, for very polar compounds such as carbohydrates, the larger molecules appear to be more efficiently ionized than with conventional electrospray.

**Atmospheric pressure chemical ionization (APCI)** APCI is another variation of electrospray where, in a similar manner to thermospray, the incorporation of a corona discharge into the spray increases the ion yield by electron stripping from both sample and solvent molecules. Much of the ion formation thus occurs by CI processes.

### Matrix-Assisted Laser Desorption/Ionization

In this technique, the sample is mixed with an ultraviolet (UV) absorbing matrix and ionized with a UV laser (Figure 11). Ions are extracted with a high potential (in the order of 20 kV) and accelerated into the mass spectrometer. The purpose of the matrix is to dilute the sample and absorb the laser energy for transmission to the sample but the exact mechanism by which this occurs is, as yet, unclear. The main products are singly charged ions such as  $[M + H]^+$ ,  $[M - H]^-$ , or  $[M + Na]^+$  (Figure 12). As the technique produces a pulsed beam, it is ideally interfaced to TOF mass spectrometers. However, magnetic sector instruments equipped with array detectors have been used and, recently, collisional cooling of the ion beam has enabled MALDI to be linked to quadrupole mass spectrometers. Commercial instruments invariably use nitrogen lasers emitting at 337 nm although several other wavelengths including those in the infrared region of the spectrum have been used. The

**Figure 9** Electrospray ion source.

**Figure 10** Electrospray spectrum of myoglobin (16951.5 Da). Measured masses of the peaks and the charge states are shown.

**Figure 11** MALDI ion source.

**Figure 12** Typical MALDI mass spectrum of a protein. The peak at  $m/z \sim 12359$  is the  $[M+H]^+$  ion. Peaks at  $m/z \sim 6183$  and  $24720$  are from the  $[M+2H]^{2+}$  ion and the dimer, respectively.

mass range of the technique is limited, not by its ability to ionize molecules but by the drop in signal with increasing mass imposed by most mass spectrometric detectors. In reality, the method is useful up to  $\sim 300$  kDa on commercial instruments although ions can sometimes be seen at much higher mass.

Most types of molecule can be ionized given a suitable matrix and a considerable amount of work

has been performed on the determination of the best matrices for various compounds. 2,5-Dihydroxybenzoic acid appears to be one of the best all-round matrices and is the standard for carbohydrates. Proteins and glycoproteins are best ionized from sinapinic acid whereas peptides give strong signals from  $\alpha$ -cyano-4-hydroxycinnamic acid. In order to obtain a spectrum, the sample is mixed with the matrix in a

ratio of roughly 1:5000 sample–matrix and allowed to crystallize on the mass spectrometry target. This target, which is usually in the form of a plate with up to several hundred sample spots, is inserted into the mass spectrometer and illuminated by the laser.

MALDI offers high sensitivity; some samples can be analyzed from as little as a few hundred attomoles applied to the target and often, after spectral acquisition, the remaining sample can be recovered. The technique is reasonably tolerant to the presence of contaminants such as salts and buffers but for strong signals these contaminants should be removed. MALDI, along with electrospray, has now become one of the major methods for examination of proteins and peptides and is extensively used in proteomic research. Measurement of synthetic polymer distributions is another growth area and large carbohydrates can be ionized without the need for derivatization as required by FAB mass spectrometry.

**Atmospheric pressure matrix-assisted laser desorption/ionization (ap-MALDI)** A variant of the conventional MALDI technique is ap-MALDI in which the sample is ionized outside the vacuum system and ions are captured through a small orifice, usually into an ion trap mass spectrometer. Its advantage appears to be a considerable amount of rapid collisional cooling of the ions by the high atmospheric pressure, leading to stabilization of sensitive compounds. On the other hand, some compounds, such as carbohydrates, appear to suffer increased fragmentation under these conditions.

**Surface enhanced laser desorption/ionization (SELDI)** SELDI is a variant of MALDI in which the MALDI probe is derivatized with various substances that have affinity for the analyte. The probes are then used to extract the analyte directly from mixtures thus avoiding sample loss through more complicated cleanup procedures. Contaminants can

be washed from the probe with appropriate buffers or solvents leaving the purified analyte ready for analysis. Many adsorbents have been used; typical examples are hydrophobic or ionic compounds, enzymes, antibodies, DNA, and various receptors. Although most applications have been reported with proteins, the technique is applicable to any type of compound for which a specific adsorbent can be attached to the probe.

Three types of SELDI are recognized, surface-enhanced affinity capture (SEAC), surface-enhanced neat desorption (SEND), and surface-enhanced photolabile attachment and release (SEPAR). With SEND, the energy-absorbing molecules typical of the MALDI process are bound to the probe surface, often covalently although, recently, porous silica has been found to be an effective SEND surface. Additional binding is involved with SEPAR and analytes are released photochemically during the ionization process. SEAC is the most widely used SELDI technique; the probe essentially acts as the purification device via affinity capture and then spectra are recorded as in MALDI following the addition of a typical MALDI matrix. Various affinity probes are now commercially available and the technique offers great potential for examination of trace material in complex biological matrices.

### Spark Source Mass Spectrometry

This is a technique for analysis of inorganic material. The sample, as a powder, is mixed with graphite and pressed into rods. Two rods carrying high potentials are placed close together such that a spark is generated between them. The result is mainly the production of atomic species such as  $\text{Mg}^{2+}$ ,  $\text{K}^+$ , and  $\text{Cl}^+$  and large numbers of elements can be analyzed simultaneously. However, the method has drawbacks such as the presence of incompletely dissociated molecular fragments and the production of ions

**Figure 13** ICP ion source.

in multiple charge states leading to very complex spectra.

### Inductively Coupled Plasma Mass Spectrometry

Most elemental analyses performed by mass spectrometry now employ inductively coupled plasma mass spectrometry (ICPMS), a technique that produced mainly singly charged ions against a very low background. Acidic solutions of the analyte, at concentrations of  $1 \mu\text{g ml}^{-1}$  or less, are sprayed axially from a nebulizer into an inductively coupled argon plasma operating in the region of 8–10 000 K. Ions are sampled through a metal sampling cone, usually nickel, with an aperture of 1–1.2 mm (Figure 13). A sampling skimmer with a  $5 \mu\text{m}$  aperture placed  $\sim 6 \text{ mm}$  behind this cone captures ions into a lens system that focuses them into the quadrupole mass spectrometer. A photon stop that casts a shadow over the final aperture into the spectrometer blocks photons that would otherwise increase the background noise.

Spectra generated by these instruments are comparatively simple because of the predominantly singly charged ions. Most of the naturally occurring elements have three or fewer isotopes and isotope overlap is minimal. There are no coincidences in mass below 40 ( $^{40}\text{Ar}$ ,  $^{40}\text{Ca}$ , and  $^{40}\text{K}$ ) and above this mass, only indium ( $^{113}\text{In}$  and  $^{115}\text{In}$ ) has no isotope free of isobaric interference. Detection limits are in the region of  $50 \text{ pg ml}^{-1}$ .

## Electron Impact and Chemical Ionization

**E Eljarrat and D Barceló**, Institut d' Investigacions Quíiques i Ambientals de Barcelona, Consejo Superior de Investigaciones Científicas, Barcelona, Spain

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Electron impact (EI) is not only the oldest but also is still the most frequently used ionization technique in environmental organic analysis. EI is, theoretically, capable of ionizing all organic compounds. The practical limitations arise from vaporizing the sample in the

source. Highly involatile compounds, with large or very polar molecules, cannot be evaporated from a probe, while thermally labile substances decompose on heating. Among the alternative ionization modes, chemical ionization (CI) is by far the most frequently used method. CI is capable of ionizing a wide range of organic molecules, although ionization efficiency varies greatly, depending upon the type and degree of functionalization. Molecules that support protonation work best, whereas hydrocarbons and haloalkanes ionize very poorly. Combined EI/CI sources have been commercially available for many years. It is of particular importance that both EI and CI sources can easily be coupled

in multiple charge states leading to very complex spectra.

### Inductively Coupled Plasma Mass Spectrometry

Most elemental analyses performed by mass spectrometry now employ inductively coupled plasma mass spectrometry (ICPMS), a technique that produced mainly singly charged ions against a very low background. Acidic solutions of the analyte, at concentrations of  $1 \mu\text{g ml}^{-1}$  or less, are sprayed axially from a nebulizer into an inductively coupled argon plasma operating in the region of 8–10 000 K. Ions are sampled through a metal sampling cone, usually nickel, with an aperture of 1–1.2 mm (Figure 13). A sampling skimmer with a  $5 \mu\text{m}$  aperture placed  $\sim 6 \text{ mm}$  behind this cone captures ions into a lens system that focuses them into the quadrupole mass spectrometer. A photon stop that casts a shadow over the final aperture into the spectrometer blocks photons that would otherwise increase the background noise.

Spectra generated by these instruments are comparatively simple because of the predominantly singly charged ions. Most of the naturally occurring elements have three or fewer isotopes and isotope overlap is minimal. There are no coincidences in mass below 40 ( $^{40}\text{Ar}$ ,  $^{40}\text{Ca}$ , and  $^{40}\text{K}$ ) and above this mass, only indium ( $^{113}\text{In}$  and  $^{115}\text{In}$ ) has no isotope free of isobaric interference. Detection limits are in the region of  $50 \text{ pg ml}^{-1}$ .

## Electron Impact and Chemical Ionization

**E Eljarrat and D Barceló**, Institut d' Investigacions Quíiques i Ambientals de Barcelona, Consejo Superior de Investigaciones Científicas, Barcelona, Spain

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Electron impact (EI) is not only the oldest but also is still the most frequently used ionization technique in environmental organic analysis. EI is, theoretically, capable of ionizing all organic compounds. The practical limitations arise from vaporizing the sample in the

source. Highly involatile compounds, with large or very polar molecules, cannot be evaporated from a probe, while thermally labile substances decompose on heating. Among the alternative ionization modes, chemical ionization (CI) is by far the most frequently used method. CI is capable of ionizing a wide range of organic molecules, although ionization efficiency varies greatly, depending upon the type and degree of functionalization. Molecules that support protonation work best, whereas hydrocarbons and haloalkanes ionize very poorly. Combined EI/CI sources have been commercially available for many years. It is of particular importance that both EI and CI sources can easily be coupled

**Table 1** Guideline to select the best ionization technique for each class of substance

Nature of sample	Ionization technique	Example
Gaseous samples and volatile thermally stable substances	EI, CI (EI may well not show a molecular ion)	CO <sub>2</sub> , NO, solvents, PAHs, dioxins
Small molecules (<1000), which are pure and sufficiently stable and volatile to desorb from a probe	EI, CI (EI may well not show a molecular ion)	Many organic molecules
Small molecules (<1500), which are not volatile or thermally stable. Molecules need to have a degree of proton affinity or potential to form a cation or an anion	FAB, if pure, from a probe. ESI or APCI online in a solvent stream, or with an LC separation if required	Amino acids, carbohydrates, lipids, and many organic molecules
Small molecules as above, which have been derivatized to give stable volatile products	EI or CI using GC online with MS	Acids as esters, alcohols as silyl ethers
Peptides, proteins, oligonucleotides	ESI from solution or online with micro-LC	Intact proteins
Proteins and peptides and mixtures of same. Polymers	MALDI	Tryptic digests. PPG, PEG
'Non-covalent' interactions	ESI (nanoflow) with MS/MS	Drug–drug or drug–protein interactions

APCI, atmospheric pressure chemical ionization; CI, chemical ionization; EI, electron impact; ESI, electrospray ionization; FAB, fast atom bombardment; GC, gas chromatography; LC, liquid chromatography; MALDI, matrix-assisted laser desorption ionization; MS, mass spectrometry; MS/MS, tandem mass spectrometry; PAHs, polycyclic aromatic hydrocarbons; PEG, polyethylene glycol; PPG, polypropylene glycol.

with capillary gas chromatography (GC), thus combining the high separation efficiency of GC with the high sensitivity and specificity of mass spectrometry (MS).

Whereas EI is an energetic ionization technique, CI is a softer ionization applied to volatile samples where no or a very small molecular ion is observed due to excessive fragmentation. For both EI and CI, the molecular weight range is 10–1000 Da. In rare cases, it is possible to analyze samples of higher molecular weight. Accuracy of the mass measurement at low resolving power is  $\pm 0.1$  Da and in the high-resolution mode,  $\pm 5$  ppm.

EI and CI methods can be used if the compound to be studied is sufficiently volatile and stable to be vaporized intact. However, only 20% of the organics found in surface water are volatile enough to be amenable to GC–EI–MS or GC–CI–MS. Today, there are a variety of other ionization techniques available: electrospray ionization (ESI), atmospheric pressure chemical ionization, matrix-assisted laser desorption ionization, and fast atom bombardment. Each of these has its advantages and disadvantages. A simple guideline to the most likely optimum ionization technique for a given class of substance is given in Table 1.

In this article, the basic theory of EI and CI is introduced. Then, some applications using both ionization techniques will be presented.

## Theory of Operation

### Electron Impact

EI is the classical ionization method in MS. The sample for analysis is introduced into the ion

**Figure 1** (A) EI ionization source and (B) CI ionization source.

source (Figure 1) (held under high vacuum,  $10^{-7}$ – $10^{-5}$  mbar) from a reservoir (in the case of gases and volatile liquids), from a heated probe (for involatile liquids and solids), or as the eluent from a GC. It is essential that the sample enters the ion source in the gaseous state and the ability to heat the source and solids probe are important to successful sample analysis. Sample molecules collide with high-energy electrons (typically 70 eV), produced by a glowing filament of either tungsten or rhenium, and if the energy transferred exceeds the molecules' ionization

energy, ions are formed. Because the pressure is kept low ( $10^{-7}$ – $10^{-5}$  mbar), ion–molecule reactions do not occur, e.g., the  $[M+H]^+$  signal due to proton transfer is not observed. Application of an extraction voltage (500–10 000 V, depending on the type of instrument) to a lens stack accelerates ions out of the source to the mass analyzer. Ionization efficiency is increased by placing the inner source between the poles of a small magnet, causing the electrons to travel with a helical trajectory.

EI ion formation is outlined in Figure 2. In this example, 20 eV is transferred to the sample molecule following its collision with a 70 eV electron. Since the ionization energy of most organic molecules is of the order of 15 eV, an electron is expelled to produce a radical cation  $M^{+\bullet}$  with 5 eV excess energy. Once formed, the radical cation can be accelerated out of the source, mass analyzed, and detected as the molecular ion. Given that the mass of an electron is trivial in comparison to that of an organic molecule, the mass of the molecular ion is effectively the molecular mass  $M_r$  of the sample. If we consider that covalent bond strength in an organic molecule is of the order of a few electron volts, any individual molecular ions possessing an internal energy greater than this level will be prone to fragmentation. In the example given in Figure 2, the molecular ion is 5 eV above the ground state and there is easily sufficient energy to cause fragmentation. Fragments may be lost as radicals or as neutral molecules. MS is only capable of detecting ions, hence neutral molecules and radicals do not appear in the spectrum.

**Figure 2** Overall reaction:  $M + e^- \rightarrow M^+ + 2e^-$ .

Since the ion source temperature (200–250°C) and the bombarding electron's energy are kept constant, the number and amount of fragments is constant for almost every mass spectrometer. Therefore, the number and amount of ionic fragments and the amount of the  $M^+$  is characteristic for each substance. For this reason, EI-MS is particularly valuable for analysis as both the molecular ion (if present) and abundant fragments can be used to characterize compounds. Library searches are extensively used to identify 'unknown' compounds. Huge mass spectral libraries are commercially available, such as the NIST Library, which contains 230 000 spectra, and the Wiley Library, with 275 000 spectra. Such libraries usually contain only EI mass spectra, which further support the importance of EI-MS. The identification process is based on search algorithms that compare the obtained spectra with those of a library. A spectral match and fit factor defines the certainty of the identification. However, not all compounds have a unique mass spectrum. For example, the EI mass spectra of such distinct compounds as 9-fluorenone and benzo(c)chinoline are almost indistinguishable. Moreover, it is often impossible to distinguish between isomers by EI-MS.

### Chemical Ionization

CI is an ionization technique similar to the classical EI but the knowledge and results of ion–molecule reactions are exploited. CI is carried out in an ion source similar to that used for EI (Figure 1). The principal difference between the two techniques is the presence, during operation in the CI mode, of a CI reagent gas (typically ammonia, methane, or isobutene). Dedicated CI sources also tend to have a narrower exit slit to maintain a higher CI gas pressure in the inner source ( $10^{-3}$ –1 mbar). Electrons from the filament ionize the CI gas in an EI source and the free radicals produced undergo various possible ion–molecule reactions with the sample molecules present in order to enhance the abundance of the molecular ion. The major reaction in positive chemical ionization (PCI) is proton transfer, which takes place in sample molecules with a higher proton affinity than the reagent ions. Other reactions that can also occur include charge exchange, if the reagent gas does not contain available hydrogen, electrophilic addition, and anion abstraction. Table 2 shows the different reactive species generated for each reagent gas normally used in CI. The major difference between isobutene CI and methane CI is the fact that protonated methane can transfer 284 kJ mol $^{-1}$  more energy during ionization than *t*-butyl cation, the main reagent ion of isobutene.

**Table 2** Different reactive species generated for each reagent gas

Reagent gas	Reactive species	Characteristics
H <sub>2</sub> CH <sub>4</sub>	H <sub>3</sub> <sup>+</sup> CH <sub>5</sub> <sup>+</sup> , C <sub>2</sub> H <sub>5</sub> <sup>+</sup>	Good for most organic compounds Usually produces [M + H] <sup>+</sup> , [M + CH <sub>3</sub> ] <sup>+</sup> adducts Adducts are not always abundant Extensive fragmentation
C <sub>2</sub> H <sub>4</sub> C <sub>3</sub> H <sub>8</sub> H <sub>2</sub> O <i>i</i> -C <sub>4</sub> H <sub>10</sub>	C <sub>2</sub> H <sub>5</sub> <sup>+</sup> C <sub>3</sub> H <sub>7</sub> <sup>+</sup> H <sub>3</sub> O <sup>+</sup> <i>t</i> -C <sub>4</sub> H <sub>9</sub> <sup>+</sup>	Usually produces [M + H] <sup>+</sup> , [M + C <sub>4</sub> H <sub>9</sub> ] <sup>+</sup> adducts and some fragmentation Adducts are relatively more abundant than for methane Not as universal as methane Fragmentation virtually absent Polar compounds produce [M + NH <sub>4</sub> ] <sup>+</sup> adducts Basic compounds produce [M + H] <sup>+</sup> adducts Non-polar and non-basic compounds are not ionized
NH <sub>3</sub>	NH <sub>4</sub> <sup>+</sup>	

**Figure 3** Positive ion CI with ammonia.

Thus, there is usually less fragmentation with isobutene than with methane. The ammonium ion can transfer a proton only to compounds with a higher proton affinity than ammonia, mainly nitrogen-containing compounds. As with EI, the sample is introduced from a reservoir, from a heated probe, or as the eluent from a GC.

The CI of ammonia is outlined in **Figure 3**. First, the ammonia radical cation is generated by EI, and this reacts with neutral ammonia to form the ammonium cation, the reactive species in ammonia CI. Once produced, NH<sub>4</sub><sup>+</sup> reacts with sample molecules by proton transfer or adduct formation. The [M + H]<sup>+</sup> and [M + NH<sub>4</sub>]<sup>+</sup> ions are often referred

to as molecular species. They have lower internal energy than radical cations produced by EI and, hence are less likely to fragment. CI is not as soft as ESI or field ionization, and some fragmentation is usually observed.

**Negative chemical ionization** Many important compounds of environmental and biological interest can produce negative ions under the right conditions. Negative ions can be produced by a number of processes. Negative ions are formed by ion–molecule reactions between sample and reagent gas ions. Such reactions include proton transfer, charge exchange, nucleophilic addition, or nucleophilic displacement. Moreover, the capture of the thermal electrons generated under CI conditions allows for the formation of molecular anions from compounds with a positive electron affinity. The electron energy is very low, and the specific energy required for electron capture depends on the molecular structure of the analyte. Electron attachment is an important mode of formation of negative ions, which frequently is used in CI. Negative ions are produced as a result of electron–molecule interactions by three general processes:

- ion-pair formation:  $e + \text{MX} \rightarrow \text{M}^+ + \text{X}^- + e$
- electron attachment:  $e + \text{MX} \rightarrow \text{MX}^-$
- dissociative electron attachment:  $e + \text{MX} \rightarrow \text{M} + \text{X}^-$

Benefits of negative CI (NCI) are efficient ionization, higher sensitivity, and less fragmentation than positive-ion EI or CI. There is also a greater selectivity for certain environmentally or biologically important compounds. The limitations are that not all volatile compounds produce negative ions and a poor reproducibility of the measurements.

### Coupling GC–MS

If a mixture is introduced into an ion source a mixed spectrum will result. If a technique that only gives a single ion from the molecule is used and if all the components of the mixture are similar in chemical structure then it is possible to do a mixture analysis; if an energetic ionization is used such as EI the presence of all the fragment ions will be confusing in the resulting spectrum. Also, if two or more very disparate components are present, the ionization of one may suppress the ionization of all the others. Thus, if possible it is best to introduce the analytes discretely from a chromatographic separation. GC is the original method linked to MS. We also have the capability to perform tandem mass spectrometry (MS/MS) with both EI and CI techniques.

## Applications for EI-MS and CI-MS

GC-MS continues to play an important role in the identification and quantification of analytes. Several ionization techniques are also used in GC-MS. Among them, EI is the most popular because it often produces both molecular and fragment ions. One important feature of EI spectra is that they are highly reproducible, which means that mass spectral libraries can be used for the identification of unknowns. However, in some cases, EI does not provide the sensitivity required for the analysis of very small amounts of compounds in environmental samples. To solve this problem, softer ionization techniques such as CI are applied. Moreover, CI is the technique of choice for the analysis of isomers, because different isomers have different reactivities toward the reagent gas, resulting in different spectra. With EI, very similar spectra are obtained for different isomer compounds.

In this section, some recent environmental examples are presented in order to view the actual applicability of each one of the ionization techniques.

### Differentiation between Isomers

CI-MS is a powerful tool for steric structure identification that often allows differentiation between isomers. In addition, compound selectivity or sensitivity can be increased by choice of reagent gases with different proton affinities and ion-molecule reaction properties. However, in practice, only few reagent gases are used such as methane or isobutene. Occasionally, ammonia with a higher proton affinity than methane is employed to enhance selectivity. Methane and argon are most frequently used in electron capture negative ionization (ECNI).

The use of less frequently applied reagent gases can result in gas-phase ion-molecule reactions that lead to increased sensitivity, selectivity, or both for certain compounds. Such reactions can be observed in ion traps (IT) at reagent gas levels of a few hundreds of ppm due to the longer residence time of the ions. CI in conventional ion sources requires a higher reagent gas pressure in the range of 0.7–2.0 mbar (0.5–1.5 Torr). This does not allow the use of corrosive reagent gases or those leading to contamination by excessive polymerization reactions.

**Polychlorinated alkane determinations** NCI has frequently been used to identify chlorinated hydrocarbons and other chlorinated compounds such as toxaphene, chlorinated paraffins, chlorinated styrenes, chlorinated diphenylethers, pentachlorophenol, chlorinated pesticides, and pesticide metabolites. Even if the molecular ion cannot be detected in all

instances, the NCI spectra are usually much simpler than the EI spectra.

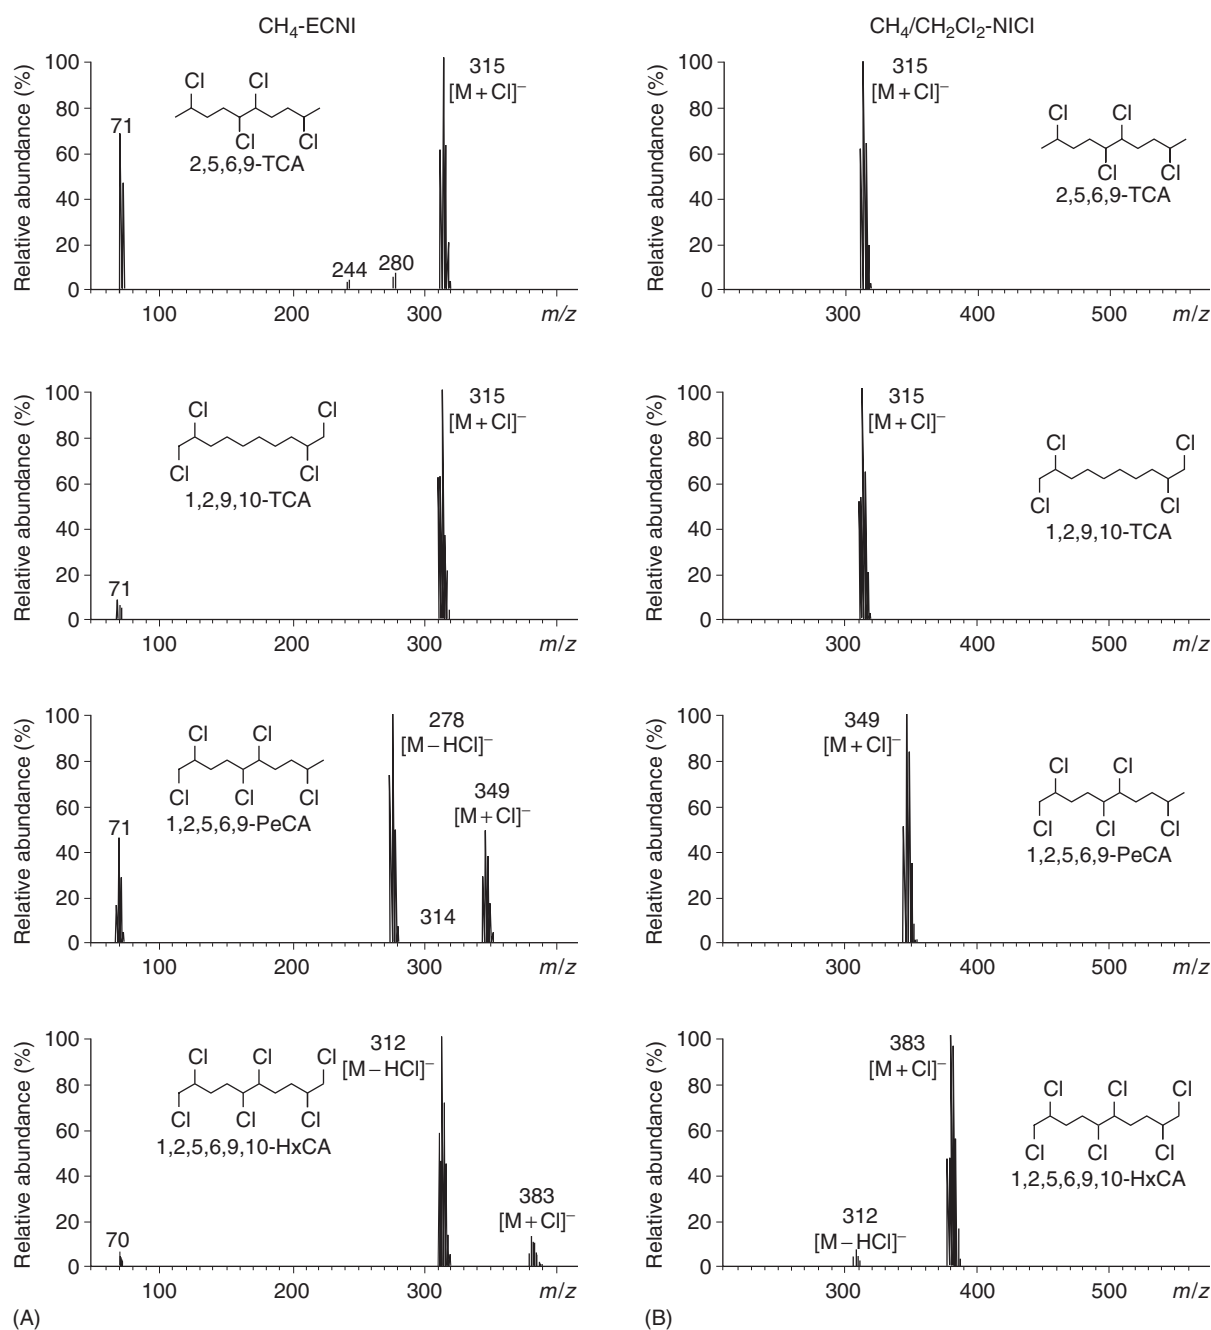

Chlorinated paraffins are complex technical mixtures consisting of polychlorinated alkanes (PCAs). The number of theoretically possible congeners, homologs, diastereomers, and enantiomers is huge (far beyond 10 000 compounds), which explains the complexity of the analysis. Most PCA analyses have been performed by GC-ECNI-MS. Methane or argon were mostly used as reagent gases. Under these conditions, the mass spectra of PCAs contain the three main ions  $[M - HCl]^-$ ,  $[M - Cl]^-$ , and  $[M + Cl]^-$ . The molecular ion  $[M]^-$  has generally an intensity of <10% (Figure 4). The use of dichloromethane/methane reagent gas mixtures is an alternative to conventional ECNI. A nearly exclusive formation of  $[M + Cl]^-$  adduct ions was observed suppressing the generation of other fragment ions and enhancing selectivity and sensitivity. Moreover, interferences from other chlorinated compounds present in environmental samples such as toxaphenes or chlordanes were suppressed.

**Polycyclic aromatic hydrocarbon determinations** Polycyclic aromatic hydrocarbons (PAHs) refer to a large and diverse group of a few hundreds of compounds with two or more fused benzene rings that are derived from endogenous and anthropogenic sources. A good number of them are known to cause cancer and genetic damage. PAHs are generally lipid-soluble, usually persistent, and in some cases bioaccumulating. Typically, these environmental pollutants arise from sources that subject organic material to high temperatures involving the incomplete combustion of such organic matter.

IT-MS combined with CI and full scan operation mode has not been frequently applied in the analysis of organic pollutants in the environment. Nevertheless, several works that compare CI and EI modes have been carried out. Methane is the most widely used chemical ionization reagent, although other compounds have also been used. For example, 1,1-difluoroethane was used as a reagent gas to differentiate PAH isomers through the formation of specific adducts by ion-molecule reaction between the cations  $CH_3CHF^+$  and  $CH_3CF_2^+$  and PAHs. This method allowed for the separation and determination of coeluting isomers.

**Lanolin steryl ester determinations** Lanolin is the wool grease secreted by the sheep sebaceous glands, and represents a complex mixture of high molecular mass lipids, including fatty acids and alcohols, sterols, hydroxyacids, diols, and aliphatic and steryl esters. Lanolin is widely used in cosmetic and pharmaceutical formulations. The study of minor lipids

**Figure 4** Mass spectra of single PCA congeners recorded with  $\text{CH}_4$ -ECNI (A) and  $\text{CH}_4/\text{CH}_2\text{Cl}_2$ -NICI (B). TCA, tetrachloroalkane; PeCA, pentachloroalkane; HxCA, hexachloroalkane. (Reprinted from Zencak Z, Reth M, and Oehme M (2003) Dichloromethane-enhanced negative ion chemical ionization for the determination of polychlorinated *n*-alkanes. *Analytical Chemistry* 75: 2487–2492; © American Chemical Society.)

has shown interest in order to assess the quality and authenticity of cosmetic and pharmaceutical products and also the steryl esters have already been used to prove the authenticity of eatable oil.

Those compounds have been reported as difficult to analyze due to their high molecular mass and poor information given by EI-MS. Also, the isomers *normal*, *iso*, and *anteiso* have been identified for each

family by means of chromatographic retention data. A comparison between different ionization techniques has been carried out in order to optimize target compound identification. EI-MS has shown to be the most sensitive but providing poor structural information for cholesteryl esters not permitting to identify the acid moiety or molecular ion. On the other hand, CI offered the best results in terms of

structural information obtained in the PCI with ammonia as reagent gas.

Several examples showed the suitability of CI versus EI in order to achieve a satisfactory separation between isomers. However, there are also some examples demonstrating that EI afforded better structural information. Fully acetylated methyl  $\alpha$ -deoxy- $\alpha$ -fluoro- $\alpha$ -D-glucopyranosides have been studied using EI and ammonia CI. Characteristic differences in the fragmentation of positional isomers were noted on analysis of the spectra, and these make it possible to determine the location of fluorine in the molecules. Fragmentation of  $[M - OCH_3]^+$  ions produced by EI provides an alternative method for localization of the fluorine atoms. On the contrary, spectra of  $[M + NH_4]^+$  cluster ions produced by CI did not afford such structural information.

### Environmental Organic Contaminants

**Phthalates** Phthalate acid esters (PAEs) are an estrogenic class of chemical compounds widely used in different industrial applications mainly as plasticizers

for polyvinyl chloride resins, adhesives, and cellulose film coatings and with minor applications in cosmetics, medical products, and insecticide carriers. They comprise a large group of compounds, several of them considered as priority pollutants: dimethyl, diethyl, dibutyl, butylbenzyl, di(2-ethylhexyl), and di-*n*-octyl phthalate. The worldwide production of PAEs  $\sim 2.7$  million metric tons a year and considerable direct (production of plastic materials) and indirect emission, via leaching and volatilization from plastic products after their usage, disposal, and incineration, explains their ubiquity in the environment.

GC-MS with EI and CI, using methane or isobutene as reagent gas has been used for the analysis of these compounds in water, soil, and sewage sludge samples. PCI with methane was found to be very useful in obtaining molecular mass information, but EI-MS is the most sensitive method. Using GC-MS in EI mode, limits of detection of  $2\text{--}30\text{ ng l}^{-1}$  in river and sea water,  $125\text{--}250\text{ ng per kg}$  in sediments, and  $10\text{--}600\text{ ng per g}$  in sewage sludge have been reported.

**Figure 5** Mass spectra of BDE-99 using NCI-MS and EI-MS approaches. (After E. Eljarrat, A. de la Cal, and D. Barceló (2003) Potential chlorinated and brominated interferences on the polybrominated diphenyl ether determinations by gas chromatography-mass spectrometry. *Journal of Chromatography A* 1008: 181–192).

**Polybrominated diphenyl ethers** Polybrominated diphenyl ethers (PBDEs) are used in large quantities for several applications due to their fire retarding properties, including electrical appliances such as television and computers, building materials, and textiles. The similarity in molecular structure of PBDEs with that of environmental toxic pollutants such as polychlorinated biphenyls and dioxins, and their resistance to degradative processes, gives rise to concern that they may lead to similar environmental problems. PBDEs are suspected to cause endocrine dysfunction by interfering with the thyroid hormone metabolism. PBDE comprises a total of 209 theoretically possible congeners. Qualitative and quantitative methods for PBDEs have been developed involving GC–NCI–MS or GC–EI–MS. Generally, NCI presents higher sensitivity than EI: NCI gave detection limits between 30 fg and 1.72 pg, whereas EI gave detection limits between 0.53 and 32.09 pg. The main advantage of EI–MS is that it provides better structural information. No structural information on the degree of bromination was obtained by NCI. The mass spectra of all PBDEs were dominated by the molecular ion  $[\text{Br}]^-$  and did not show any molecular ion. However, the EI provided better structural information, giving the molecular ions and the sequential losses of bromine atoms (Figure 5). Furthermore, it allows the quantification by isotopic dilution technique whereas NCI does not, making the analysis more reliable at trace levels.

**Selenium stable isotopes** Selenium is recognized as an essential trace element for humans. Se status is determined by dietary Se intake and its bioavailability. Se bioavailability can be estimated by assessing absorption and retention of Se stable isotopes. These studies require analytical techniques that allow precise and accurate determination of stable isotope ratios at low levels of total selenium.

Stable isotopes of Se were determined by different analytical techniques; however, GC–MS is probably the most widely used technique. GC–MS employs

selective derivatization of selenite, with an aromatic *o*-diamine to form in acidic medium a volatile piazselenole. The piazselenole is extracted into an organic solvent and analyzed by GC–MS. The analysis using EI as ionization mode was first described; however, NCI was also tested for this kind of determination. Analytical characteristics of the NCI method demonstrated the ability of this technique to accurately determine total Se and Se isotope ratios in biological samples. The detection limit for any selenium isotope was found to be 1 pg for NCI and 90 pg for EI. This technique can be applied to determine absorption and retention of Se in humans, and due to its lower detection limit compared to EI, NCI is preferential when the sample size is small (e.g., biological samples from infants).

## Introduction

Mass spectrometer ion sources are normally located inside a high-vacuum envelope. Such low-pressure ion sources, which can make use of a range of different ionization methods, are in routine use in

analytical mass spectrometers. An ion source operating at atmospheric pressure is better suited, if not essential for a growing number of applications. Whilst atmospheric pressure ionization (API) mass spectrometry (MS) was originally developed during the 1960s, it was the refinements made some 20 years later that initiated an explosion of interest in the technique. Early applications of API included direct monitoring of air for the mass-selective analysis of pollutants, explosives, and illegal drugs. The subsequent development of liquid introduction systems and modifications to the ions source, ion optics, and vacuum systems resulted in ionization techniques that were orders of magnitude more sensitive than established liquid-phase ionization techniques. In addition, these developments expanded the range of polarity and thermal lability of samples that could be analyzed. The major advantage to emerge was the increase in molecular mass range of samples amenable to MS by orders of magnitude from 15 kDa to beyond 1 MDa. Established chromatographic separation methods are now readily coupled to mass spectrometers with atmospheric pressure ion sources. As API opened new areas of mass spectrometric analysis, the technique rapidly became established, generating both qualitative and quantitative mass spectrometric data with unmatched sensitivity.

## Instrumentation

### The Combination of Ionization at Atmospheric Pressure with Separation of Ions in Vacuum

In a mass spectrometer that is used for organic analysis, the ion source is located inside a high-vacuum envelope. Such an ion source, which makes use of electron impact or chemical ionization, can conveniently and efficiently emit sample ions into a mass analyzer, which also operates under a high vacuum. The combination of an API source with a mass analyzer requires a  $10^7$ - to  $10^8$ -fold pressure reduction along the ion passageway between the source and the mass analyzer, a demanding task for the vacuum pumping system. The most common layout of an API mass spectrometer is shown in Figure 1.

When a gas expands into a vacuum, strong cooling takes place. This effect is widely used for the spectroscopic study of 'cold' molecules. When a mixture of ions and gas and water or solvent vapor expands into vacuum the cooling in the expansion region will promote the formation of ion-solvent clusters that may be so large that they fall outside the mass range of the mass analyzer:

Different instrument designs address this clustering problem in different ways: by keeping water and solvent vapor away from the vacuum system by a gas curtain or countercurrent flow of nitrogen, by keeping the source at an elevated temperature, or by breaking the initially formed clusters.

Figure 2 depicts a typical arrangement of an ion source equipped with a gas curtain. The space between the curtain plate and the orifice plate is at atmospheric pressure and is flushed with dry nitrogen. Part of the nitrogen flows to the left into the ionization region of the source, sweeping neutrals such as water molecules or dust particles to the left. Under the influence of the electric field between the curtain plate and the orifice plate ions are moved to the right toward the orifice plate. There the ions are entrained in the flow of dry nitrogen into the vacuum system. Since water and other polar molecules

**Figure 2** Curtain gas arrangement for the prevention of solvent vapor from entering the vacuum envelope of the mass spectrometer.

cannot penetrate the opening in the curtain plate, the formation of ion–solvent clusters is prevented.

The undesired formation of ion–solvent clusters is due to the temperature drop in the expansion into the vacuum system. By heating the source, or using of a heated tube for the passage of sample ions from the source into the vacuum, the temperature in the expansion region will not reach such a low value, and ions may cluster with only a few molecules, which can be removed in the expansion region by moderately energetic collisions.

### Mass Analyzers

Initial API studies were performed on quadrupole instruments with either single- or triple-stage analyzers and the first commercial instruments were also of this form. The next most popular combination is API with an ion trap mass analyzer. Time-of-flight (TOF) mass analyzers offer medium resolution that is sufficient for accurate mass determination in many cases. TOF also allows the observation of high  $m/z$  ions generated from noncovalently bound complexes of proteins. For high-resolution API, the Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer is an excellent instrument. Magnetic sector mass spectrometers have found limited application in API, because of the technical complexity of the combination of an API source with the necessary high accelerating voltage. The interest in magnetic sector instruments with an extended mass range that were developed for fast atom bombardment and field desorption has been reduced since the advent of electrospray. High-molecular-mass materials can readily be detected either by electrospray ionization on quadrupoles and TOF analyzers, or by matrix-assisted laser desorption ionization (MALDI).

### Tandem Mass Spectrometry (MS/MS)

Full-scan API spectra can be accumulated to generate molecular mass information, but in order to generate fragment ions of significant intensity it is usually necessary to use one of two commonly applied methods.

First, if a multiple mass analyzer instrument is used, the pseudomolecular ion can be collided with a stream of gas to generate collisionally induced dissociation (CID) and the formation of structurally significant fragment ions. MS/MS with selected reaction monitoring in a triple quadrupole is the method of choice for quantitation. Structure determination or confirmation is done by means of any of the available MS/MS fragmentation techniques: triple quadrupole, ion trap, quadrupole-TOF, or FT-ICR.

Second, an alternative method for the generation of fragmentation is to increase the electric field

**Figure 3** Collision-induced dissociation of ions inside the first and second vacuum stages of an API mass spectrometer.

strength between elements of the ion path inside the vacuum regions between the atmospheric pressure source and the mass analyzer (Figure 3). This ‘up front’ CID method is oftentimes incorrectly called ‘in source CID’. It can have the dramatic effect of changing the spectrum from being dominated by ions related to the intact analyte to one containing many intense fragment ions. If spectra are acquired at each of two potentials the spectra will be complementary. This ‘poor man’s MS/MS’ technique is of limited application for direct mixture analysis, but a single mass analyzer can be operated very effectively in this way during liquid chromatography–mass spectrometry (LC–MS) analysis to generate fragmentation that can be related to a particular component.

If ‘up front’ fragmentation is used in combination with real MS/MS instrumentation, the fragments of ions generated just outside the source can be fragmented again in the collision cell, resulting in spectra of MS/MS/MS type.

The most widely used method of achieving multiple, consecutive fragmentations is the repeated isolation and fragmentation inside a quadrupole ion trap.

### Techniques for Ionization at Atmospheric Pressure

The considerations given above about ion transport, declustering, fragmentation, and mass separation are independent from the way ions are generated in the API source.

Sample ions can be formed in the gas phase by the ionization of sample vapor, or can be taken from the condensed phase, which is either the liquid phase (sample in solution) or the solid phase (sample in a solid matrix).

#### Atmospheric Pressure Chemical Ionization

The development of API has yielded atmospheric pressure chemical ionization (APCI) with unique

application in high-sensitivity analysis of organic compounds. Air monitoring was one of the original fields of application of APCI-MS. Suppliers of research-grade gases use APCI for the determination of impurities at trace levels. APCI is a gas-phase ionization technique that makes use of ion-molecule reactions between reactant ions and sample molecules. Early APCI-MS instrumentation used a  $^{63}\text{Ni}$   $\beta$ -emitter or a corona discharge to ionize the sample. Modifications to the corona discharge system have produced the modern APCI instrumentation. Problems of the addition of solvent ions to the analyte to form ion clusters were alleviated by the use of a stream of gas before the mass analyzer vacuum and the application of electric field to induce collisional decomposition of such clusters (Figures 2 and 3). A further refinement of a heated nebulizer resulted in a practical, robust ionization technique capable of accepting flow rates up to  $2\text{ ml min}^{-1}$  with detection limits often in the femtogram region (Figure 4).

Ionization in positive-ion mode occurs by reaction of the solute with protonated solvent molecules, generally giving rise to an intense protonated analyte molecule or pseudomolecular ion. If ammonium salts are added to the solvent, ammonium adducts may be observed. This can be exploited to yield molecular mass information in cases where the protonated molecule readily fragments or there is an absence of basic sites at which protonation can occur.

Ions are generated in the negative-ion mode by proton abstraction by oxygen ions or by the formation of adducts with anions such as acetate or chloride present in the sample.

APCI is a gas-phase ionization technique, which requires that a sample is completely evaporated before ionization can take place. Thus, APCI can be applied to samples that do not decompose upon heating during evaporation.

The impact of APCI has been enhanced by its compatibility with separation techniques routinely used in the analysis of organic compounds.

**Figure 4** Atmospheric pressure chemical ionization source with corona discharge needle and heated nebulizer interface for combined liquid chromatography-mass spectrometry. (Reprinted with permission from *Trends in Analytical Chemistry* 13 (1994), 81; © Elsevier.)

## Atmospheric Pressure Photoionization

APCI is mostly done by means of protonation or deprotonation. If gas-phase basicity or acidity is too low for these acid-base reactions, the association with ammonium ions, formate ions, or acetate ions can be used to generate sample ions. Many samples do not have polar functional groups required for such ion-molecule reactions.

High-energy photons can remove an electron from a sample molecule and generate a molecular ion. Inexpensive gas discharge lamps, originally developed for photoionization detection in gas chromatography, are suitable sources of photons, e.g., 10.0 eV photons from a krypton discharge lamp.

Since most solvents used in reversed-phase LC have ionization energies above 10.0 eV, while many organic molecules of interest have an ionization energy below 10.0 eV, it is possible, in principle, to selectively ionize a sample. Atmospheric pressure photoionization (APPI) is a new technique first published in 2000, but has already been developed into a commercial product. APPI is a gas-phase ionization technique, which requires that a sample is completely evaporated before ionization can take place. Thus, APPI can be applied to samples that do not decompose upon heating during evaporation.

## Electrospray

In parallel with the development of APCI, investigations were being made into a process by which a solution is sprayed into a high electric field at atmospheric pressure (Figure 5). Charged droplets result from the nebulization of the solution in an electric field, with both solvent and solute ions being detected resulting in the technique referred to as electrospray ionization (ESI). ESI is a liquid-phase ionization technique. It does not involve the evaporation of a neutral sample, so the input of heat is not required. Therefore, ESI is the method of choice for the ionization of samples that would decompose under the input of heat for evaporation. Because ESI

**Figure 5** Principle of electrospray ionization inside an atmospheric pressure ion source.

makes use of sample ions in solution, the composition of the sample solution has to be adjusted in order to convert a neutral sample into a sample ion in solution. Basic samples, for example, are ionized by the addition of an acid to the solution.

Refinement by the use of a nebulizing gas and a cross-flow of hot gas allows high liquid flow rates to be used. The high sensitivity of the technique and compatibility with liquid separation methods gave rise to much interest in the pharmaceutical applications of the technique, but an explosion of interest was initiated by the observation that high-molecular-mass compounds of biological interest could be ionized with great efficiency and readily detected on instrumentation previously considered to be of low mass range. This was possible as larger molecules were subject to multiple protonation or deprotonation. Thus, whilst a peptide of molecular mass 1000 Da may be protonated once, a 3000 Da sample may be protonated three times, and a protein of molecular mass 17 000 Da 17 times (Figure 6). The resulting mass-to-charge ratios, as recorded by mass analyzers, are below  $m/z$  2000 and within the mass range of a medium-specification instrument. In addition to increasing sensitivity, electrospray effectively extended the mass range of materials amenable to MS by more than an order of magnitude to beyond 150 kDa. Subsequent work was concentrated in two fields of applications: qualitative and quantitative analysis of small molecules in the pharmaceutical industry and the newly accessible area of protein analysis. It is now apparent that electrospray, APCI, and APPI are inherently more sensitive and reliable than thermospray and fast atom bombardment. The latter two methods have essentially become obsolete for LC-MS.

**Figure 6** Electrospray mass spectrum of the protein myoglobin, FW 16950. The numbers at the peaks denote the number of charges on the ions.

### Nanoelectrospray (Nanospray)

In its original form, ESI was suitable for liquid flow rates between 1 and  $10 \mu\text{l min}^{-1}$ . Pneumatic assistance allowed flow rates up to  $50 \mu\text{l min}^{-1}$  with operation at room temperature. A further increase of flow rate requires the input of heat for the desolvation of charged droplets in order to promote the release of free sample ions.

An unexpected feature of ESI is its behavior as a concentration-sensitive detector in LC. The ion signal in ESI depends on sample concentration, not on the amount of sample per unit time passing through the source. This implies that a reduction of liquid flow rate of a given sample solution does not decrease the signal. However, by working at  $50 \text{ nl min}^{-1}$  instead of  $5 \mu\text{l min}^{-1}$  one can spend 100 times as much time on recording mass spectra from the same volume of sample solution. Thus, one can increase sensitivity by multichannel averaging of many spectra, or perform a number of different fragmentation experiments.

ESI hardware has to be adapted for low flow rate operation. The so-called nanospray systems are commercially available and can be used both for infusion of a small volume of a sample solution, and for the combination with microbore and nanobore HPLC columns.

Nanospray is used extensively in the field of proteomics.

### Atmospheric Pressure MALDI

Because of the large installed base of API instruments there is an opportunity to try and use the source and mass analyzer for new techniques and applications. One such technique is MALDI, which is normally combined with TOF mass separation under vacuum. AP-MALDI can be combined with ion traps and quadrupoles to give a low-cost expansion of the capabilities of those instruments, in particular in laboratories that cannot justify the purchase of several instruments dedicated to a specific task. AP-MALDI on an ion trap is a cost-effective way of obtaining fragmentation in combination with MALDI.

## Interfacing Separation Sciences to API Techniques

### APCI

Of the API techniques, APCI is readily amenable for online mass spectrometric detection with LC separation methods. The heated nebulizer interface can accommodate aqueous mobile phases of up to 100% water at flow rates of up to  $2 \text{ ml min}^{-1}$ . As volatile buffers can be used with the interface, many LC

separation methods can be employed without modification. Low levels of nonvolatile additives in the eluent can be tolerated for a limited time, but not in long series of samples in LC-MS/MS quantitation. Judicious choice of solvents and additives will enhance sensitivity of APCI, or at least avoid a serious loss of efficiency of sample ionization. Relative gas phase basicity and acidity of sample and solvents should be taken into account.

If thermal degradation occurs one has to use ESI instead of APCI. Supercritical fluid chromatography can also be readily linked to APCI without major modification to the chromatograph or the separation method as the ion source is designed to operate at high pressure.

### APPI

The next gas-phase ionization technique for LC-MS is APPI. It is a relatively new method, and its strengths and weaknesses will become clear as the number of applications grows over time. Thus far APPI appears to work best at flow rates of 100–200  $\mu\text{L min}^{-1}$ . At higher flow rates ionization efficiency is reduced. To increase sensitivity a dopant such as acetone, toluene, or anisole is introduced into the ionization region. First, the dopant is ionized by photons and next the dopant ions undergo ion-molecule reactions with ultimate ionization of the sample. Solvent components can have a major influence on the cascade of ion-molecule reactions, and should be selected with care.

### Electrospray

As electrospray can be used without the input of heat, this is the method of choice for the detection of thermally labile materials resolved by separation techniques. Flow rates of up to 50  $\mu\text{L min}^{-1}$  can be taken into the pneumatically assisted ESI interface at room temperature. Ion sources capable of operating with up to 1  $\text{mL min}^{-1}$  include a cross-flow of hot gas. A simple splitting device can be used at high flow rate conditions. The excess flow can be diverted for online detection using an alternative detection method or a fraction collector can be used to allow offline studies. Although 100% aqueous solutions can be sprayed there is loss in sensitivity; this can often be avoided by the use of a postcolumn make-up solvent containing a high proportion of organic liquid.

The fact that the interface can operate at low flow rates is an advantage in that micro-LC can be directly coupled for situations where the amount of sample is limited. Suitability for low flow rate studies enables capillary electrophoresis (CE) to be interfaced to the electrospray ion source. Despite the low sample

loadings associated with CE, selected ion monitoring detection of compounds can be performed with an increasing number of analyses involving the acquisition of full scan spectra. This is clearly an immense aid to CE studies as the nature of the separation precludes the use of most other qualitative techniques from both on- or offline analysis.

## Applications of APCI, APPI, and ESI

### Analytical Biotechnology

The greatest impact of electrospray has been in analytical biotechnology, as this is a new area of mass spectrometric study rather than an existing area in which sensitivity has been increased. The electrospray spectrum of a protein consists of an envelope of ions originating from protein molecules possessing different numbers of protons and hence mass-to-charge ratios. The number of charges on a molecule is linked to the number of basic sites and hence to the molecular mass. An injection of 5 pmol of protein dissolved in 10  $\mu\text{L}$  of solvent will produce an intense spectrum. In order to calculate the molecular mass of the protein, one of several algorithms can be used. The simplest involves the calculation of the molecular mass from the mass-to-charge ratios of two adjacent charge states. If the lower charge state is  $n$ , then the mass-to-charge ratio ( $m_1$ ) of this lower charge state is

$$m_1 = \frac{M + n}{n}$$

where  $M$  is the molecular mass of the compound.

For the higher charge state ( $n + 1$ ), the mass-to-charge ratio  $m_2$  is given by

$$m_2 = \frac{M + (n + 1)}{(n + 1)}$$

Then the number of charges and the molecular mass can be calculated from these two equations with two unknowns. This takes account of the charging species, usually protons. The system is self-checking as several charge states are observed and each adjacent pair will produce a mass measurement. The complete mass calculation process is normally performed by the mass spectrometer data system. Contamination of a protein with buffer salts or with detergents is a serious problem in electrospray. MALDI is more flexible in this respect.

Although of great value, accurate molecular mass measurement is only part of the protein characterization process. In order to confirm a protein sequence the material can be digested to produce peptides that can in turn be characterized by MALDI

or LC–MS. Electrospray is the preferred option for molecular mass determination or, if used in conjunction with LC–MS/MS, for peptide sequencing. In addition to amino acid sequence information, electrospray can be used to improve the detection and characterization of post-translational modifications including N- and C-terminal derivatization, phosphorylation, and, by analysis of peptide with and without a reducing agent, disulfide bonding. Using a combination of traditional carbohydrate analysis techniques and electrospray, the site and nature of protein glycosylation may also be determined.

Being a very soft ionization technique, electrospray does not disrupt noncovalent bonds in complexes in solution. Complexes of an enzyme with a substrate, enzyme with inhibitor, and conglomerates of proteins can be detected by ESI. This development has led to the examination of protein–protein interactions by means of ESI MS.

Conformational changes of proteins may be observed by either studying the number of protons that can be placed on a protein or by determining the number of exchangeable protons by also acquiring data in deuterated solvents and subtracting the calculated molecular masses. This can also be performed in real time, allowing the observation of conformational changes as they occur in biochemical systems.

### **Drug Discovery**

Many applications in drug discovery have evolved from methodology originally developed in analytical biotechnology. In addition to the mass spectrometric analysis of potential therapeutic agents, drug targets may be observed directly by electrospray, which can be exploited to investigate the mode of action of drugs with the aim of designing more effective products. This application includes the measurement of enzyme inhibition or the interaction of a drug with a receptor by simply observing the increase in molecular mass using ESI upon incubation of the enzyme or receptor protein with an appropriate inhibitor or drug. As data can be acquired in a matter of minutes, enzyme–inhibitor or receptor–drug reactions may be studied in real time and thus kinetic data can be derived by plotting the concentration of components against time.

### **Drug Development**

The increased sensitivity available from API techniques, either electrospray or APCI, has enabled lower levels of impurities found in drug substances, or their intermediates, to be characterized by LC–MS without time-consuming isolation of components of

interest. This information in turn allows the modification and optimization of a process to yield the pure drug substance.

### **Drug Quantitation and Metabolism Studies**

Again, the sensitivity of API techniques and the range of samples amenable has been exploited, allowing the detection, characterization, and quantification of drugs and metabolites present in amounts orders of magnitude less than earlier mass spectrometric methods. APCI, ESI, and recently APPI are now used for such ADME (administration, distribution, metabolism, excretion) studies. Although either ionization technique can be used in many cases, the preferred method depends on the type of material to be analyzed; thermally labile materials show molecular mass information by electrospray whereas many small polar molecules show greatest response by APCI or APPI. Probably the majority of triple quadrupole LC–MS/MS instruments in the field is in use for quantitation of drugs and metabolites. Quantitative LC–MS/MS information exceeding the limits of detection of LC with UV absorption is acquired by selected reaction monitoring. Contract labs perform a major part of such quantitations.

### **Natural Product Structure Elucidation**

The sensitivity of API techniques and the compatibility with LC make API ideal for studies when the amount of sample available is limited. In addition to molecular mass determination, MS/MS spectra containing structurally significant data can be generated from sub-picomole amounts of sample. The wide range of materials amenable to electrospray in terms of polarity, molecular mass, and thermal lability endorse electrospray as a first choice for such investigations. Given appropriate chromatographic separations, LC–MS with one of the API techniques can be used as a routine, rapid screening device with the searching of databases by molecular mass and ultraviolet absorption (also acquired on-line) to determine readily whether the components of interest have been previously observed. Chemical techniques such as derivatization or hydrolysis can be used with LC–MS and LC–MS/MS to yield further information relating to the structure of the material of interest.

## Introduction

In the past 15 years, electrospray ionization has become one of the most important ionization methods in mass spectrometry. It is the method of choice in the coupling of liquid chromatography (LC) and mass spectrometry (MS). By estimation, it is used in over 90% of all LC–MS applications. It is especially useful in the analysis of highly polar, ionic, and macromolecular analytes. In addition, electrospray ionization plays an important role in the characterization of biomacromolecules, especially peptides and proteins. History, principle, instrumentation, practical aspects, and application of electrospray ionization are discussed in this article.

## Principle of Operation

The use of electrospray nebulization and ionization in MS is based on atmospheric pressure ionization. The column effluent from a reversed-phase LC, i.e., a solvent mixture of methanol or acetonitrile and up to  $10 \text{ mmol l}^{-1}$  aqueous buffer, is nebulized into an atmospheric-pressure ion source region. Because pure electrospray nebulization can only be achieved at low flow rates, i.e., typically up to  $10 \mu\text{l min}^{-1}$ , pneumatically assisted electrospray is performed in most cases: the liquid flow is nebulized into small droplets by a combined action of a strong electric

potential between needle and counter-electrode, e.g., 3 kV, and a high-speed concurrent nitrogen flow ( $50\text{--}100 \text{ l h}^{-1}$ ). The electrospray nebulization process results in the formation of small charged droplets, positively charged droplets when the source is operated in positive-ion mode and negatively charged droplets in the negative-ion mode. In their flight between needle and counter-electrode, neutral solvent molecules will evaporate from the surface of the charged droplets. The evaporation of the solvent results in a decreasing droplet size, which in turn leads to shorter distances between the charges at the surface of the droplets. When the surface tension of the liquid can no longer accommodate the Coulomb repulsion between the charges, the droplets will disintegrate by means of a so-called Coulomb explosion or field-induced electrohydrodynamic disintegration process. This leads to the emission of a number of microdroplets with a radius of less than 10% of that of the initial droplets. Gas-phase analyte ions are generated from these microdroplets by a variety of processes, including ion evaporation, soft desolvation, and chemical ionization at the droplet surface (see below). Subsequently, the gas-phase ions can be mass analyzed.

## History of Electrospray Ionization

Although electrospray nebulization was already described in 1917 by Zeleny, the first applications of electrospray in MS date from the late 1960s, when the group of Dole investigated the transfer of macromolecules from the liquid phase to the gas phase by electrospraying dilute solutions in a nitrogen bath

## Introduction

In the past 15 years, electrospray ionization has become one of the most important ionization methods in mass spectrometry. It is the method of choice in the coupling of liquid chromatography (LC) and mass spectrometry (MS). By estimation, it is used in over 90% of all LC–MS applications. It is especially useful in the analysis of highly polar, ionic, and macromolecular analytes. In addition, electrospray ionization plays an important role in the characterization of biomacromolecules, especially peptides and proteins. History, principle, instrumentation, practical aspects, and application of electrospray ionization are discussed in this article.

## Principle of Operation

The use of electrospray nebulization and ionization in MS is based on atmospheric pressure ionization. The column effluent from a reversed-phase LC, i.e., a solvent mixture of methanol or acetonitrile and up to  $10 \text{ mmol l}^{-1}$  aqueous buffer, is nebulized into an atmospheric-pressure ion source region. Because pure electrospray nebulization can only be achieved at low flow rates, i.e., typically up to  $10 \mu\text{l min}^{-1}$ , pneumatically assisted electrospray is performed in most cases: the liquid flow is nebulized into small droplets by a combined action of a strong electric

potential between needle and counter-electrode, e.g., 3 kV, and a high-speed concurrent nitrogen flow ( $50\text{--}100 \text{ l h}^{-1}$ ). The electrospray nebulization process results in the formation of small charged droplets, positively charged droplets when the source is operated in positive-ion mode and negatively charged droplets in the negative-ion mode. In their flight between needle and counter-electrode, neutral solvent molecules will evaporate from the surface of the charged droplets. The evaporation of the solvent results in a decreasing droplet size, which in turn leads to shorter distances between the charges at the surface of the droplets. When the surface tension of the liquid can no longer accommodate the Coulomb repulsion between the charges, the droplets will disintegrate by means of a so-called Coulomb explosion or field-induced electrohydrodynamic disintegration process. This leads to the emission of a number of microdroplets with a radius of less than 10% of that of the initial droplets. Gas-phase analyte ions are generated from these microdroplets by a variety of processes, including ion evaporation, soft desolvation, and chemical ionization at the droplet surface (see below). Subsequently, the gas-phase ions can be mass analyzed.

## History of Electrospray Ionization

Although electrospray nebulization was already described in 1917 by Zeleny, the first applications of electrospray in MS date from the late 1960s, when the group of Dole investigated the transfer of macromolecules from the liquid phase to the gas phase by electrospraying dilute solutions in a nitrogen bath

gas. Their hypothesis was that gas-phase ions from macromolecules can be produced by desolvation of the charged droplets produced in electrospray, assuming these macromolecules exist as preformed ions in solution, e.g., positively charged proteins at a pH below their isoelectric point. This ionization mechanism is nowadays called the charge residue model.

After the work of Dole, where the sample solutions were sprayed in an atmospheric-pressure region, a variety of other related approaches have been described. In the mid-1970s, the group of Evans investigated the applicability of electrospraying solutions in vacuum. The method is called electrohydrodynamic ionization. As the result of the interaction of a strong electrostatic field with a liquid meniscus at the end of a capillary tube, solvated ions are emitted from the apex of a so-called Taylor cone, formed at the capillary tip. Due to the high-vacuum conditions, the use of nonvolatile organic solvents, e.g., glycerol doped with sodium iodide to increase the conductivity, is required for analyte introduction. Compounds investigated are saccharides, nucleosides, and small peptides. Ions are formed by attachment of a cation or an anion to the analyte molecules. In 1980, the group of Zolotai reported similar experiments using glycerol or water as solvent and introduced the term 'field evaporation of ions from solution'.

An important contribution to this field was made by Iribarne and Thomson in the late 1970s, who investigated the processes of the direct emission of ions from liquid droplets. In their experimental setup, a liquid solution is pneumatically nebulized in an atmospheric-pressure chamber and the droplets produced are charged by random statistical charging using an induction electrode positioned close to the nebulizer. Solvated singly charged ions are formed in the evaporating spray, which are sampled into a differentially pumped quadrupole mass spectrometer. Their theoretical description of the ionization process, i.e., the so-called ion-evaporation model, was adapted later by researchers in the field of thermospray and electrospray ionization.

The ion formation in thermospray ionization, introduced in the early 1980s by Vestal and co-workers, was explained in terms of ion evaporation. Preformed analyte ions are evaporated from small, fast-evaporating, charged droplets generated by the thermospray nebulization process. Although the importance of ion evaporation in thermospray ionization is questioned, the emphasis put at it at the time certainly stimulated further investigation into liquid-based ionization approaches for MS.

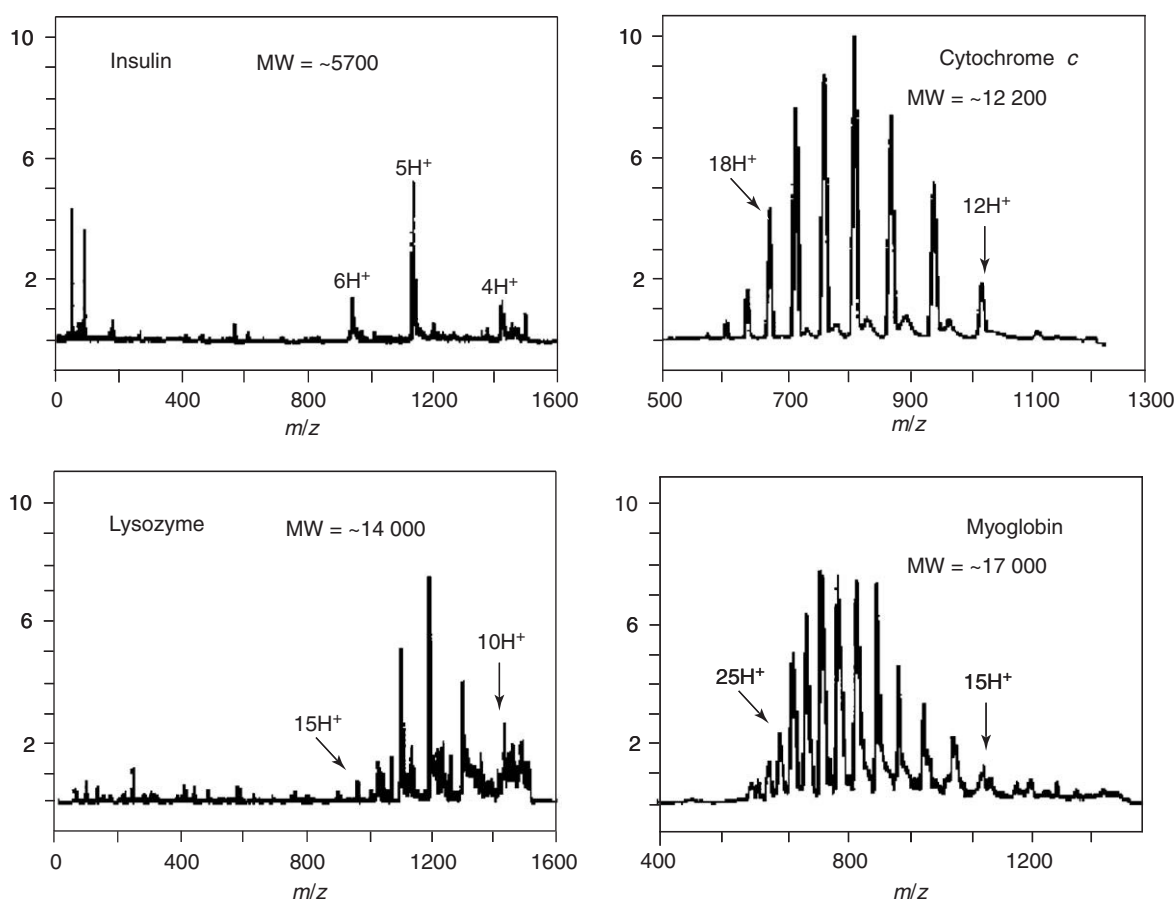

Within this context, Yamashita and Fenn, in the mid-1980s, continued the original electrospray

experiments of Dole and implemented molecular beam technology to solve some of the experimental difficulties experienced by Dole. The liquid is electrosprayed into a bath gas. The dispersion of ions, solvent vapor, and bath gas is expanded into a vacuum chamber, forming a supersonic jet, the core of which is sampled into the mass spectrometer by means of a skimmer. Initially, they tried in vain to reproduce the experiments of Dole with biomacromolecules, but nevertheless continued to investigate the sequence of electrospraying and droplet evaporation with low molecular mass compounds. They concluded that the hypothesis of Dole was not valid in their experiment and they recognized the importance of the work of Iribarne and Thomson in this field. The major breakthrough in this research was achieved in 1988, when the formation of multiply charged protein ions was demonstrated (Figure 1). This revolutionized the application of MS, because biomacromolecules could now be analyzed using simple and relatively low-cost quadrupole mass analyzers. In 2002, Fenn received the Nobel price for chemistry for his contribution to mass spectrometric analysis and characterization of biomacromolecules.

Although Fenn initially emphasized the importance of ion evaporation in ion formation by electrospray ionization, extensive research has demonstrated that, depending on the analyte and the experimental conditions, the charge-residue model and the ion-evaporation model are both important. In addition, especially in the analysis of small molecules, gas-phase ion-molecule reactions appear to play an important role in ion formation by electrospray ionization.

## Instrumentation

After the first demonstration of multiply charged gas-phase proteins ions, all major instrument manufacturers developed atmospheric-pressure ion sources, equipped with electrospray interfaces for both protein characterization and LC-MS applications. Within 5 years, electrospray interfacing became the method of choice in LC-MS coupling. It led to a large increase in the use of MS for the characterization and identification of labile and polar analytes as well as to routine quantitative analysis. The advent of electrospray ionization for peptide and protein analysis stimulated further development and analytical application of existing and new mass analysis approaches, such as quadrupole ion traps, Fourier-transform ion-cyclotron resonance MS, and quadrupole-time-of-flight hybrid instruments. It opened new application areas, such as proteomics. LC-MS

**Figure 1** First spectra demonstrating multiply charged proteins generated by electrospray ionization mass spectrometry. (Reprinted with permission from Mann M, Meng CK, and Fenn JB (1989) Interpreting mass spectra of multiply charged ions. *Analytical Chemistry* 61: 1702; © American Chemical Society.)

with electrospray ionization and in selected-reaction monitoring (SRM) mode in triple-quadrupole MS-MS instruments has become the method of choice in routine quantitative bioanalysis supporting preclinical and clinical studies within the pharmaceutical industry as well as in many other areas.

Since the first introduction of commercial electrospray interfaces for LC-MS, based on the Fenn design, continuous developments have taken place, resulting in more reliable and robust as well as more efficient interfaces. Some aspects of these developments are briefly discussed here.

An atmospheric-pressure ion source for electrospray ionization consists of five parts (**Figure 2**): (1) the pneumatically assisted electrospray needle, used for the introduction of sample solution or LC mobile phase; (2) the actual ion source region, where ions are generated from the microdroplets at atmospheric pressure; (3) the ion-sampling aperture; (4) the atmospheric-pressure to high-vacuum interface; and (5) the ion-optical system, where the ions generated in the source are analyte-enriched and transported toward the high-vacuum mass analyzer.

**Figure 2** Schematic diagram of an atmospheric-pressure ionization interface.

In principle, two types of electrospray interfaces must be distinguished. Most attention is paid to the high-flow devices applied for routine LC-MS. However, an extreme low flow electrospray needle device, i.e., the so-called nanoelectrospray, has been developed as well, especially by Mann in the mid-1990s. Nanoelectrospray is especially important in

the low nanoliter per minute introduction of protein and peptide solutions, but is increasingly important in the coupling to MS of micro- and nano-LC and capillary electromigration techniques, such as capillary electrophoresis and isoelectric focusing. Many precautions described below for the high-flow devices are not necessary in the low-flow devices.

Different instrument manufacturers have developed a wide variety of ion source and interface designs. Initially, the electrospray needle was positioned axial with the ion-sampling orifice. Due to the heavy use of electrospray LC-MS in high-throughput quantitative bioanalysis, alternative positions had to be investigated, in order to prevent a rapid contamination of the ion-sampling orifice by nonvolatiles in the liquid stream. The liquid introduction needle is nowadays positioned orthogonal to the ion-sampling orifice. In addition, a countercurrent nitrogen flow is applied around the ion-sampling orifice to further protect it against precipitation of nonvolatile contaminants. The increase in the flow rate of the liquid introduced by means of pneumatically assisted electrospray required the supply of heat to the spray in order to stimulate the solvent evaporation from the droplets. In most systems, this is achieved by the application of heated nitrogen streams, either concurrent, orthogonal to the spray, like in turbo-ion-spray, or countercurrent. In addition, the ion source block and ion-sampling orifice are heated.

The glass capillary with two-sided conductive layers, as introduced by Fenn, is still applied as the ion-sampling device in some of the commercial interfaces. However, a variety of other ion-sampling devices have been introduced, including orifices in flat plates and sample cones as well as heated stainless-steel capillaries.

While initially only one differentially pumped stage between atmospheric-pressure ion source and mass analyzer was applied, two or even three pumping stages are used in current systems. Significant effort has been put in increasing the pumping speed at the transition zone, partly in order to increase the size of the ion-sampling orifice. Significant progress has been made in turbomolecular pumps, enabling the use of small and relatively efficient dual-inlet pumps in small bench-top LC-MS systems. Skimmers are used between the various pumping regions. In the relatively large pumping regions, evacuated by turbomolecular pumps, a variety of RF-only multipole devices are used, e.g., quadrupole, hexapoles, octapoles, and ion tunnels. These devices are used to transport the ions through these pumping regions and to focus them into the mass analyzer.

## Practical Aspects

Successful operation of the electrospray interface requires the optimization of a variety of interrelated ion-source parameters. In addition, the solvent composition and flow rate may influence the system performance.

### Ion-Source Parameters

The ion-source parameters and their optimum values depend on the specific electrospray ionization source applied, e.g., in some source designs the optimum voltage difference between needle and counter-electrode is around 4.5–5 kV, while in other designs the optimum is around 3 kV. Most systems nowadays allow for an automatic optimization of the voltages in the source and in the mass spectrometer. These procedures search for optimum ion production and transmission toward the detector. In addition, the ion transitions to be used in SRM in quantitative analysis can be optimized in this way. Although very useful, the procedures do not account for the important influence of mobile-phase composition and sample effects on the performance of the electrospray interface.

### Solvent Composition

Both the solvent composition and interfering contaminants in the sample solution can have distinct influence on the electrospray ionization efficiency for a particular analyte. In general, reversed-phase-type mobile phases are applied, i.e., mixtures of water and either methanol or acetonitrile containing an acid, base, or buffer. It is often found that most analytes show better response from solutions containing >50% organic solvent (methanol or acetonitrile in most cases). However, electrospray ionization is not possible from pure organic solvents. Obviously, the organic content of the mobile phase in LC-MS is more determined by retention characteristics in LC than by ionization and MS detection. It has been demonstrated for a large variety of compounds that a methanol-containing mobile phase leads to a better response than an acetonitrile-containing mobile phase. Postcolumn and/or sheath-flow addition of high-organic solvents, such as aqueous mixtures with 2-propanol or methoxyethanol, are sometimes applied, especially in the analysis of proteins by electrospray ionization MS.

### Electrolyte Additives

The composition, pH, and concentration of the buffer used also influences the performance of the electrospray interface. Based on the ionization

mechanisms, briefly outlined above, one would conclude that an acidic mobile phase is needed in the analysis of an organic base and a basic solution for an organic acid. In this way, the formation of liquid-phase preformed ions is promoted. However, in the electrospray MS analysis of especially small molecules (<1 kDa), the picture appears to be more complex. Wrong-way-around electrospray has been described, where organic bases are ionized from basic solutions in positive-ion mode without significant loss in response.

Although most of the current LC-MS interfaces can readily cope with nonvolatile mobile-phase additives such as sodium phosphate buffers, they should not be used in routine LC-MS applications. They may lead to more pronounced adduct formation and may lead to significant suppression of the response. Therefore, the use of volatile additives is recommended.

Recently, Mallet and co-workers investigated the influence of a number of mobile-phase additives on the response of eight basic drugs in positive-ion mode and eight acidic drugs in negative-ion mode. The influence of formic, acetic, and trifluoroacetic acids, and ammonium hydroxide, formate, biphosphonate, and bicarbonate were investigated as a function of additive concentration. Some of their results are shown in Figure 3. The ionization of all compounds, both basic and acidic ones, was found to be suppressed by the addition of strong ion-pairing agents like trifluoroacetic acid or nonafluoropentadecanoic acid. Most compounds respond similarly to the addition of acetic acid and formic acid, although the effect is compound dependent. In positive-ion mode, some compounds (propranolol, trimethoprim, terfenadine, methoxyverapamil, and reserpine) show ion enhancement at acid concentrations below 0.5%, while others show ion suppression (risperidone and benextramine). Somewhat surprisingly, the response of some bases (risperidone, terfenadine, methoxyverapamil, benextramine) is enhanced by addition of ammonium hydroxide. The quaternary ammonium compound piperizolate is not significantly influenced by additions of ammonium hydroxide or formic or acetic acids. Most basic compounds are suppressed by the addition of ammonium formate, bicarbonate, and biphosphonate. In negative-ion mode, most compounds are ion suppressed by formic and acetic acid additives. Ammonium hydroxide results in (significant) ion enhancement for cholic acid, raffinose, canrenoic acid, while fumaric acid, malic acid, and etidronic acid are strongly suppressed. The response of cholic acid, raffinose, and canrenoic acid is also enhanced by ammonium formate and bicarbonate. Ammonium biphosphate suppresses the response of all acidic compounds.

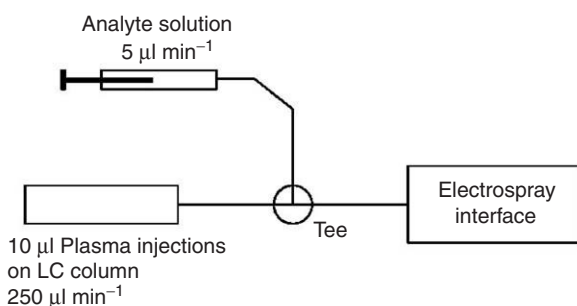

**Figure 3** Effect of additives, formic acid (FA), trifluoroacetic acid (TFA), ammonium hydroxide (NH<sub>4</sub>OH), and acetic acid (AcOH) on the relative response of (A) propranolol and (B) risperidone in electrospray ionization (compared to 50% aqueous methanol, which is 100%). (Data from Mallet CR, Lu Z, and Mazzeo JR (2004) *Rapid Communications in Mass Spectrometry* 18: 49.)

### Detergents

The influence of various detergents on the electrospray ionization of proteins was also investigated in some detail. The detergents are frequently required for the solubilization of the proteins. At concentrations of 0.01% or below, only sodium dodecyl sulfate and taurocholate show significant suppression. At 0.1%, most of the detergents result in significant suppression, e.g., to below 10% for sodium dodecyl sulfate and taurocholate, CTAB, LDAO, and Triton X-100, to the 10–30% range for sodium cholate, and various alkyl glucosides, and to the 30–60% range for CHAPS, hexyl and dodecyl glucosides.

### Sample Interferences

In quantitative analysis, further ion suppression or enhancement may be due to coeluting sample constituents not removed by the sample pretreatment. In

**Figure 4** Schematic diagram of the experimental setup for the study of matrix ion-suppression effects in electrospray ionization mass spectrometry. (Based on Bonfiglio R *et al.* (1999) *Rapid Communications in Mass Spectrometry* 13: 1175.)

most cases, the identity of such components is not clear. It has been demonstrated that nonvolatile residues in the pretreated plasma or urine samples cause ion suppression or enhancement. If the suppression is not too severe, i.e., not compromising the method detection limit too much, it would not be of significant importance. However, it is found that the suppression effects are not reproducible from sample batch to sample batch. Recently, such effects have been studied in detail by analyzing five different plasma batches. Poor relative standard deviations (%RSD) were found for the analyte in electrospray ionization, while the analog internal standard was showing good %RSD. It was found that this effect results from highly erroneous peak area values for the analyte in one of the five plasma batches. Because the internal standard peak area was not affected, and all samples could be analyzed with good %RSD by means of atmospheric-pressure chemical ionization, it was concluded that an unknown interference must be present in one of the plasma batches. Similar effects have been reported by many others. Based on these results, Matuszewski *et al.* proposed that evaluation of ion suppression by matrix effects should not be performed using just one plasma batch, but rather by evaluating the effect in five independent plasma batches.

When in method development and validation a matrix effect is observed which compromises the reliability of the method (poor %RSD), further attention must be paid to improving the sample pretreatment method. The T-in method shown in Figure 4 may be of great help in such investigations: the effect of eluting sample constituents on the response of a continuously infused analyte solution is evaluated.

### Concluding Remarks

Being a liquid-phase ionization method, the performance of electrospray ionization can be significantly

influenced by the solvent composition, especially mobile-phase additives and sample interferences. Nevertheless, electrospray ionization can be successfully applied in the (quantitative) analysis of samples from various application areas. In most cases, the method development for electrospray LC-MS is easier to perform than for LC-UV. However, one should keep in mind that these two detection techniques respond differently to interfering compounds, and therefore require a different optimization strategy. With proper validation, LC-MS is a powerful approach to quantitative analysis. Care must be taken in the selection of mobile-phase additives and in sample pretreatment.

### Applications

The advent of electrospray ionization certainly opened many new application areas for mass spectrometric analysis. This is based on the ability to provide extreme soft liquid-based ionization. Perhaps the most important application area is the analysis of peptides and proteins. The possibility to perform rapid molecular-weight determination of proteins up to 200 kDa stimulated the commercial availability of MS instrumentation featuring atmospheric-pressure ion sources, equipped with electrospray ionization. Other application areas benefited from these developments. LC-MS has become an important analytical tool in many areas of drug development within the pharmaceutical industry, in the study of natural products in plants, in food and environmental analysis. It is about to enter the clinical application area for therapeutic drug monitoring, systematic toxicological analysis, and monitoring of inherited metabolic diseases.

As indicated, electrospray ionization plays an important role in the characterization of proteins. In this area, electrospray ionization is competed by matrix-assisted laser desorption ionization (MALDI), which in some cases appears to be less prone to suppression effects to sample constituents and/or additives. First of all, the formation of multiply charged ions of proteins enables the accurate determination of the protein molecular weight, generally within 0.1% accuracy. The ion envelope of multiply charged proteins ions can actually be a disadvantage, especially in the analysis of proteins with significant heterogeneity due to, for instance, post-translational glycosylation. In current protein research, the determination of the molecular weight of the intact protein appears to play a less important role. In most cases, the protein is enzymatically digested to a peptide mixture. The mass spectrometric characterization of this mixture leads to a peptide map. Due to its ability to produce

singly charged ions, MALDI is preferred in most cases in initial research. Data from the peptide map are applied to a protein database search in an attempt to identify the protein. If further studies are required to identify the protein, e.g., peptide sequencing by means of tandem mass spectrometry (MS/MS), the use of electrospray is often more favorable, because it is coupled more readily to triple-quadrupole or quadrupole–time-of-flight hybrid instruments.

The identification and quantification of proteins in complex biological samples is especially important in the current proteomics research. While for many years MALDI was the method of choice, because of the ease with which it is combined to two-dimensional gel electrophoresis, the role of electrospray ionization in combination with multidimensional LC is increasing.

Already in the early applications of electrospray in the analysis of proteins it was found that electrospray ionization can significantly contribute to the study of protein conformation in solution. While initially solvent-induced conformational changes were investigated, such studies were extended by the use of hydrogen/deuterium exchange and other gas-phase reactions. More recently, ion-mobility spectrometry was implemented between the electrospray ion source and the mass spectrometer as a powerful tool in the assessment of conformational changes of proteins. Such tools are not only applied in fundamental studies, but also applied to detection and monitoring of changes in protein conformation related to, for instance, neurodegenerative diseases like Alzheimer, Parkinson, and Creutzfeldt-Jacobs diseases.

Another important application area of electrospray ionization is the study of noncovalent complexes between proteins and inhibitors, cofactors, metal ions, carbohydrates, other peptides and proteins, substrates, and of nucleic acid complexes. In most cases such complexes exhibit relatively low charge states, resulting in high  $m/z$ . In most cases, the study of such complexes requires the use of either modified quadrupole mass analyzers, to enlarge their  $m/z$  range, or time-of-flight instrument, which show an inherent larger  $m/z$  range. For example, the group of Naylor examined the binding of the calcium-binding protein calmodulin to the calmodulin-dependent protein kinase II (CamK-II) and to melittin. Both peptides form equimolar complexes with calmodulin only in the presence of calcium (stoichiometry was 1:1:4 for calmodulin:peptide:Ca). A typical spectrum of the calmodulin/melittin complex is shown in **Figure 5**. These type of studies are relevant both in the field of structural biology and in the field of drug discovery, enabling the study of drug–protein or inhibitor–protein interactions.

**Figure 5** Negative ion electrospray ionization mass spectrum of calmodulin ( $50 \mu\text{mol l}^{-1}$ ) in the presence of melittin ( $50 \mu\text{mol l}^{-1}$ ) and  $100 \mu\text{mol l}^{-1}$  calcium acetate, pH 5.7. Ions in the range between  $m/z$  900 and 1600 represent uncomplexed calmodulin and ions in the range between  $m/z$  1700 and 3000 represent the noncovalent calmodulin/melittin complex. ## Liquid Secondary Ion Mass Spectrometry

N J Haskins, Hants, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Liquid secondary-ion mass spectrometry (liquid SIMS) is an obsolescent ionization technique that revolutionized the analyses of large biological molecules in the 1980s. The term includes fast atom bombardment mass spectrometry (FAB-MS). The technique has been largely superseded by electrospray ionization. This account will cover the history of the technique, the principles of the operation, and the development of continuous flow systems allowing a degree of liquid chromatography–mass spectrometry operation and cover the application of the technique, especially to polar and large molecules such as peptides and small proteins.

### The Development of Liquid SIMS

Liquid SIMS grew out of the development of secondary-ion mass spectrometry. In this technique, ionized atomic or molecular particles are analyzed following their emission from a surface after bombardment with a beam of energetic primary particles. This primary beam may be composed of electrons, ions, fast neutrals, or photons. Secondary ions were observed as early as 1910 by J.J. Thomson after bombarding a metal surface with a beam of ions, but the use of SIMS as an analytical tool came into common use in the 1970s. In this mode of operation, a high-energy beam of ions was directed at a surface to obtain a high yield of secondary ions. The surface itself was eroded quite rapidly. The technique was used especially to study the surface layers of metals and silicon wafers in the growing electronics industry. This technique is known as dynamic SIMS.

To analyze material absorbed on a surface required a less energetic primary beam that would not disrupt the crystalline structure of the substrate. This technique was described as static SIMS. Problems arose inasmuch poorly conducting substrates would become charged, disrupting the primary beam and the emission of secondary ions. Vickerman and co-workers showed in 1979 that the use of a fast atom beam, a stream of energetic neutrals, reduced the charging problem and improved the stability of the secondary ion beam. They called their technique fast atom bombardment SIMS or FAB SIMS. The technique was taken up by Barber and co-workers for the analysis of

intractable organic molecules, and rapidly evolved thereafter into liquid SIMS.

Barber was working at a time when it was required to have a sample in the gas phase before ionization, which is not possible for biologically important materials that are involatile, thermally unstable, and often charged. The most obvious classes are peptides and proteins that are massive, fragile, and often very polar. Some techniques existed for studying these types of samples by introduction in the solid phase and the most used techniques in the 1970s were probably field desorption, static SIMS, and LASER-induced desorption. All these techniques had difficulties with their use and often gave irreproducible results. Barber used static SIMS by coating targets with a thin layer of deposited sample and subjecting this surface to a beam of argon ions with 2–5 keV energy. Both positive and negative ion spectra could be obtained but the sputtered ions leaving the surface had considerable energy spread reducing resolution, and surface charging was a continuing problem. Barber developed a small source producing a beam of fast argon atoms with 2–8 keV energy to strike the sample. Spectra were obtained by depositing a solution of sample on a copper target and introducing this into the fast atom beam. A chance observation showed that spectra could be much improved if the target was covered with an involatile oil (typically glycerol) and the sample dissolved in this. Not only were more stable spectra obtained but also the sample lifetime was considerably extended. Spectra were obtained in both positive and negative ionization modes. The technique was called fast atom bombardment mass spectrometry.

It was quickly realized that it was not essential to use a ‘pure’ atom beam. Acidified glycerol was a sufficiently good conductor where charging of the surface did not occur and several groups, such as M-Scan Ltd. in the UK, developed simpler sources relying on generating beams of fast ions for the primary beam. Initially, gas sources were used for generating beams of xenon ions with energies of 8–10 keV. It was shown that the intensity of the secondary beam depended on the atomic weight of the primary ions, i.e., xenon > argon > neon. Later sources used cesium to generate a primary beam of cesium ions with very high energy (20–30 keV).

The high voltages used to generate the primary beam and hence the secondary beam plus the high concentration of sputtered neutral molecules made magnetic sector instruments the most ideal mass analyzer to use with liquid SIMS sources. Linear

instruments such as quadrupoles are affected by noise from neutrals whilst other analyzers requiring higher vacuum (such as FT-ICR-MS) are badly affected by the relatively high gas pressures.

The use of ion beams precluded the use of the term FAB and the family of techniques became known as liquid SIMS.

## Structure and Operation of the Liquid SIMS System

The liquid SIMS system comprises a target stage mounted on the tip of an introduction probe, a source for the primary ionization beam (commonly known as a 'gun'), and a source comprising beam focusing, extraction, and exit lenses to shape the secondary ion beam and inject it into the mass analyzer (Figure 1).

The target stage originally comprised a thin steel plate mounted on two contact legs in early sources,

Figure 1 Schematic of a FAB source.

although later more robust solid blocks were used. In operation, the target would be covered with a film of involatile oil known as the 'matrix' in which the sample was dissolved. Matrix materials became an art with special recipes for some selected applications but in the main most samples could be analyzed using a matrix of acidified glycerol. For some biomolecules, thioglycerol or a mixture of thioglycerol and glycerol gave better results whilst *m*-nitrobenzyl alcohol was useful for some apolar compounds that did not dissolve in the hydrophilic matrices. Acidification was usually accomplished using acetic or hydrochloric acid, although occasionally thioacetic was used. In order to obtain good spectra it was essential to ensure that the sample remained in solution within the matrix. Samples were usually added dissolved in a suitable solvent; experience showed that alcohols (methanol, ethanol) and dimethylsulfoxide were useful. Halocarbon solvents were unsuitable as they created flashovers and generally gave weak, noisy spectra.

The primary beams could be generated using three types of guns. Initial work by Barber used a fast atom generator, but later authors used ion guns either using xenon or cesium.

The fast atom generator is a device (Figure 2) in which argon gas is first ionized and accelerated toward the target, then passes through a collision cell in which charge exchange occurs between the fast-moving argon ions and slow argon atoms. This produces a mixed beam of fast and slow argon atoms and ions. After ejection from the gun the remaining ions are deflected from the beam whilst the slow argon atoms diffuse and are lost. The accelerating and exit electrodes are aluminum and erode during use and this type of gun requires cleaning and replacement of these parts every so often. The beam of mainly fast argon atoms hits the surface of the matrix causing sputtering and the expulsion of sample ions (see below).

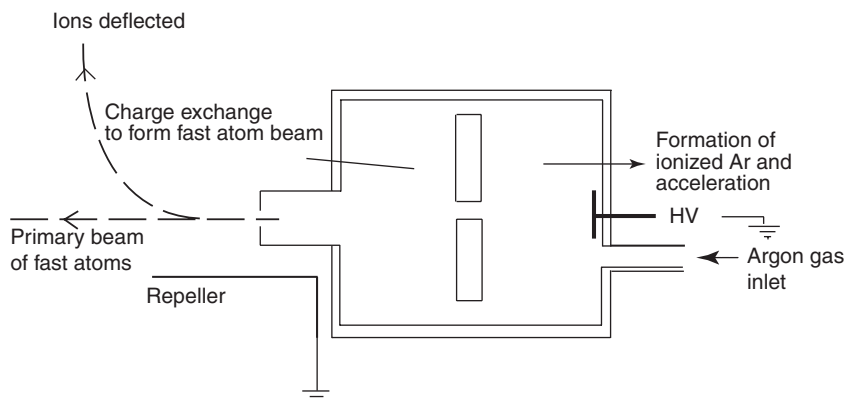

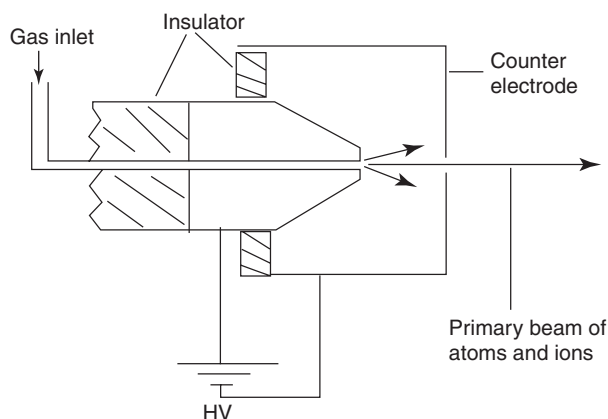

Figure 2 Schematic for a fast atom gun.

The need for a fast atom beam was not necessary as the target was connected into an electrical circuit and the matrix was sufficiently conducting so that surface charging effects caused by using a fast ion beam no longer occurred. Consequently, an alternative primary ion device was developed that used a simple charged nozzle to ionize a jet of gas ions. Gas at a flow rate of  $0.5 \text{ ml min}^{-1}$  passes through a nozzle with a narrow orifice that is held at high voltage to a cap (counter electrode) with an exit hole. Experiments with various gases showed that the intensity of the secondary ion beam depended on the mass of the bombarding gas and therefore xenon was used as the gas of choice. However, the flow of gas into the source chamber was higher than that from the fast atom gun, and care was required to avoid tripping the high vacuum (Figure 3).

The final development of a primary ion source was the cesium ion gun. A pellet of cesium iodide molded around a pin is heated to allow the salt to flow. A high voltage is applied (25–30 kV) and a beam of fast moving cesium ions is formed, which is extracted and focused onto the target through a series of lenses. The great advantage of this type of device is the very low load of gas in the source chamber. The disadvantage is the very high voltages employed, which require special generators and insulators to prevent electrical breakdowns.

All three types of guns generate a beam of high-velocity particles (either atoms or ions). These hit the surface of the matrix with considerable energy and disrupt the surface layers. Any ions contained within the surface layers are sputtered away and, as the target is held at the accelerating voltage for the mass spectrometer, are accelerated through conventional beam shaping optics into the mass analyzer. Holding the target with a positive charge allows the analysis of positive ions, while a negative charge allows the negative ions. With ion guns the accelerating energy

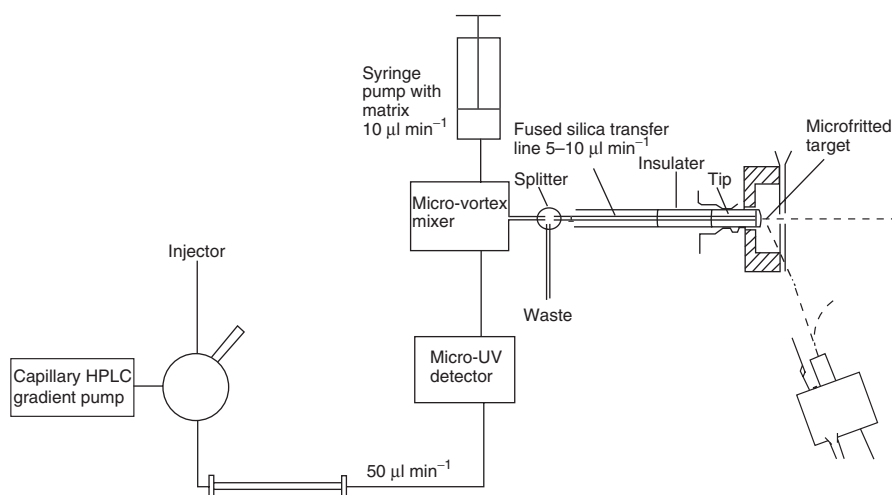

**Figure 3** Schematic for an ion gun.

of the incident beam needs to be greater than the accelerating voltage applied to the target. Thus, in a typical sector instrument with an accelerating voltage of 6 or 8 kV, the incident beam needs to be at least 8 keV. Cesium guns usually operate at much higher voltages so no problems arise with these sources.

The amount of energy released by the incident beam is sufficiently high in the vicinity of the point of impact that sample molecules are ionized by proton transfer from a protonated matrix. Typically, the spectrum obtained shows cluster ions formed from the matrix. In particular, the positive ion spectrum of glycerol (mw 92 u) shows a series of ions  $92n + 1$  where  $n$  can be 1 up to 12 or more. This spectrum can be used to calibrate the mass spectrometer and also provide internal lock masses for accurate mass measurement, described in applications below.

A modified target is used with capillary high-performance liquid chromatography systems, developed by Ito in 1985. In this target, a fused silica line brings the effluent from the liquid chromatogram to a diffuser in the target (Figure 4). This was a difficult technique to operate because flows to the tip had to be kept very low ( $< 1 \mu\text{l min}^{-1}$ ) and the matrix (usually glycerol) had to be added postcolumn. The effluent from a capillary LC system was mixed with a solution of matrix and the combined solution, containing perhaps 10% glycerol by volume, passed through a splitter to keep the flow to the mass spectrometer within limits. The complete system was described as dynamic FAB. The simple system was developed by various manufacturers, especially JEOL and Micromass. The ultimate probe tips had a diffusing mesh across the end of the capillary with an annular wick of tissue outside this to trap excess liquid. The tip was warmed slightly to aid evaporation of liquid from the wick. Results were obtained and published using these systems but it was difficult to retain chromatographic resolution and the quality of the spectra was not great. Data were obtained on tryptic digests of proteins using these techniques, which allowed accurate mass measurements using some polyethylene glycol as internal calibrant. This study showed that dynamic FAB could produce a stable ion beam but better results were obtained by collecting chromatographic fractions offline, concentrating these, and running as normal samples. This aspect of liquid SIMS has been completely superseded by capillary electrospray sources, introduced in the 1990s. Electrospray gave better sensitivity and the generation of multiply charged ions allowed the analysis of much larger molecules than FAB, which usually tends to give protonated molecules.

All liquid SIMS sources work in the same fashion. The primary beam impacts the surface of a liquid

**Figure 4** Schematic for a dynamic FAB probe for LC-MS.

matrix. At the point of impact considerable energy is released, disrupting the lattice of molecules of the matrix making up the meniscus. Indeed, the energy at the point of impact is sufficient to cause molecular fragmentation, so for glycerol successive losses of water are observed (the protonated molecule for glycerol has  $m/z$  93 u; fragments are observed at  $m/z$  75 and 57 u). The impact sputters protonated species away from the surface, both from the matrix and from any analyte molecules contained within the surface layers. If the analyte exists as a protonated species within the matrix then these cations are analyzed directly. Otherwise the energy of the impacting beam allows proton transfer between the protonated matrix and neutral species just above the surface of the matrix. Further away from the impact point clusters are sputtered with insufficient energy to break apart. This is clearly observed for glycerol where a sequence of cluster ions is observed having mass  $92n + 1$ ,  $n$  ranging from 2 up to 15–20. The sequence is sufficiently stable to act as an internal calibrant for accurate mass measurements (see below).

The matrix may contain traces of metal cations, especially alkali metals such as  $\text{Li}^+$ ,  $\text{Na}^+$ , and  $\text{K}^+$ . In these cases, cluster ions are observed for analytes of the type  $\text{M} + \text{Na}^+$ . These are often accompanied by  $\text{M} + \text{K}^+$ , giving a sequence of ions  $\text{M} + 1^+$ ,  $\text{M} + 23^+$ , and  $\text{M} + 39^+$ .

Negative ions can also be observed by reversing the polarities within the ion source and the target. The primary beam remains positive. Deprotonated species are sputtered in a manner analogous to the cationized species. Clusters are sometimes observed such as  $\text{M} + \text{Cl}^-$ .

The elegance of liquid SIMS is that after such disruptive events the surface is restored by the flow of liquid matrix. Further, the conducting properties

mean that any charge buildup in the meniscus is conducted away to the electrically connected target stage. Thus, a sample can be analyzed for as long as liquid remains on the target, often for minutes on end. Spectra can be accumulated by a data system improving the signal-to-noise ratio.

Sample intensity depends on the atomic mass of the bombarding gas. In experiments with both fast atom and ion guns the intensity of the signal was in the approximate ratio of 1:0.28:0.15 for xenon, argon, and neon, respectively (the ratio of atomic masses is 1:0.30:0.15). The approximately linear relationship between atomic mass and intensity is as expected.

Accurate mass measurement could be carried out using suitable calibrants. A popular calibration compound was polyethylene glycol, a mixture of polymers of the form  $\text{H}(\text{OCH}_2\text{CH}_2)_n\text{OH}$ . This commonly used oil has a series of protonated molecules with 44 u spacing, e.g., 151, 195, 239, 283, 372, etc. It also gave a similar negative ion series (149, 193, 237, etc.). Other calibrants were glycerol itself, relying on a series of cluster ions of mass  $92n + 1$  in positive ion mode, and  $92n - 1$  in negative ion mode. High mass calibration was carried out using various alkaline iodide salts, especially cesium iodide with clusters of  $(\text{CsI})_n\text{Cs}^+$  in positive mode and  $(\text{CsI})_n\text{I}^-$  in negative ion mode.

## Some Applications of Liquid SIMS

From the start liquid SIMS was used for the analysis of important biological molecules that, due to their polarity or their mass, were not amenable to existing mass spectral methods. This was exemplified in Barber's original presentation at the Chemical Society Symposium on Soft Ionization Biological Mass

Spectrometry held at Imperial College, London, in July 1980, which was the first announcement of the FAB technique. Barber's examples included a glycoside antibiotic (bluensomycin), a dinucleotide, some penicillins, and some peptides, including gastrin with a molecular weight of almost 2000 Da. These examples set the main application areas for liquid SIMS. The development of high-field magnetic sector instruments with mass ranges up to 10 000 u, and fitted with liquid SIMS sources, revolutionized the analysis of peptides and proteins in the 1980s at a time when the young biotechnology industry required these analyses to be done.

Confirmation of the primary structure of peptides and proteins generated using recombinant DNA was rapidly identified as an important application. Indeed, using a magnetic sector instrument, accurate mass measurements could be carried out. In an early case using peak matching and a resolution of 10 000 the mass of a recombinant octapeptide

(Ac-thr-glu-gly-phe-ser-glu-leu-lys-OH) was determined as 952.4691. The calculated mass for  $C_{42}H_{66}N_9O_{16}$ , the protonated molecule, was 952.4628.

For larger engineered proteins a combination of enzymatic digestion and analysis of the mixture of peptides formed was used to confirm the primary structure of engineered proteins. Simple programs were written to predict the expected masses of the peptides formed and any overlaps due to partial cleavages. The technique was termed 'FAB mapping' in 1981. It was especially useful in determining whether any point mutations had taken place in the sequence of a recombinant protein or if partial cleavage of N- or C-terminal amino acids had taken place, a phenomenon known as 'ragged ends'.

In a typical experiment a protein would be subjected to enzymatic digestion using an enzyme such as trypsin, which cleaves the amino acid chain on the C-terminal side of lysine or arginine. This produces a

**Figure 5** The fragment ions formed by cleavages involving the peptide bond from protonated peptides following ionization using a liquid SIMS source.

mixture of peptides comprising not only the peptide chains between arginine and lysine residues but also lesser amounts of chains comprising two or more residues due to partial cleavage. The probability of two peptides having the same mass is low, so the 'map' produced is an accurate quality control tool for monitoring the presence of the correct components in the protein sequence. If any discrepancies occur, further maps, using different enzymes giving different mixtures of peptides, can be used to identify a point mutation. Additionally, microchemical manipulation such as methylation or acetylation can be carried out on the probe tip to give additional information. In these cases, it is often useful to use a mixed stable isotopically labeled reagent to give a clear marker signal, for example, acetylation with a 1:1 mixture of  $\text{CH}_3\text{CO}$  and  $\text{C}^2\text{H}_3\text{CO}$  markers. The mass shift and isotopic pattern immediately highlights the number of added acetate groups for each tryptic peptide. This technique was used in the 1980s for monitoring the quality of recombinant insulins and interferons.

Similar techniques were used for determining the structures of unknown peptides and proteins but in these cases the individual peptides were isolated and the primary sequence determined. The mass spectral fragmentation of peptides occurs principally at the peptide linkages and can give rise to six fragment ion types. A nomenclature for this fragmentation (see

Figure 5) was proposed by Roepstorff and Fohlman in 1985, and has been accepted as a standard since. In the early 1980s, many reports appeared describing the primary structures of peptides that had been derived using a combination of liquid SIMS sources and magnetic sector mass spectrometers. Spectra were produced using MS/MS techniques as well as the spectra from single sector analysis. These spectra were marked by a series of ions spaced with the residual mass of the amino acid residue lost and were easy to read. Only two pairs of amino acids had the same residual mass, namely leucine and isoleucine (isomers with residual mass 113), and glutamine and lysine (different formulae but same nominal mass 128). An example is the spectrum of the C-terminal y-ions from  $\alpha$ -endorphin generated using an ion -gun and a mixed glycerol/thioglycerol matrix (Figure 6).

The revolution in the use of mass spectrometry was extended to other biopolymers, especially sugars. Most enzymes consist of a protein molecule that is modified by the attachment of polysaccharides. The structure of these sugar residues can be vital for the activity of the enzyme and liquid SIMS was used, often in the negative ion mode, to study these. An example showing the fragmentation of two isomeric sugars is shown in Figure 7.

Although the combination of liquid SIMS and magnetic sector mass spectrometry gave rise to the

**Figure 6** The fragmentation of  $\alpha$ -endorphin protonated molecule after FAB ionization (1984; example provided by M-Scan Ltd.).

**Figure 7** The fragmentation patterns induced after FAB ionization that distinguishes two isomeric sugars (1984; example provided by M-Scan Ltd.).

use of mass spectrometry as, arguably, the most important analytical tool for biochemistry, by itself this technique is almost obsolete. The development of atmospheric pressure electrospray (ESI), then micro-electrospray sources, and of analyzers such as orthogonal axis time-of-flight (oa-ToF) has allowed analysis of biopolymers to become a routine in most biology research laboratories. Amenable to the application of sophisticated computing programs to

control the whole system, from separation and introduction devices to complex MS/MS experiments, the ESI-oa-ToF combination is capable of automated analyses on very small quantities of material, far exceeding the sensitivity of liquid SIMS.

### Introduction

Matrix-assisted laser desorption/ionization (MALDI) is a relatively new ionization technique that is capable of ionizing a large variety of compounds, particularly large proteins, for analysis by mass spectrometry. Its introduction, together with electrospray ionization in the late 1980s, extended the mass range of molecules that could be examined by mass spectrometry into the low megadalton range and provided a new tool that could be used for analysis of both biopolymers and synthetic polymers. The technique is comparatively simple to use; the sample is mixed with an excess of a suitable matrix, usually

a solid, and ionized with pulses from a laser (**Figure 1**). Ion detection is usually, but not exclusively, achieved by use of a time-of-flight (TOF) mass spectrometer. The purpose of the matrix is mainly to dilute the sample and dissipate the laser energy; however, the details of the ionization process are still poorly understood and subject to intensive research. The technique is capable of high-throughput spectral recording and typical target plates, such as those used for proteomics, can accommodate several hundred samples. Since its introduction, MALDI has become one of the major techniques for ionizing organic molecules and has largely replaced older, less sensitive, methods such as fast-atom bombardment. This article briefly reviews the technique and describes applications to several compound types.

Two variations of MALDI mass spectrometry were invented almost simultaneously in the late 1980s. In

### Introduction

Matrix-assisted laser desorption/ionization (MALDI) is a relatively new ionization technique that is capable of ionizing a large variety of compounds, particularly large proteins, for analysis by mass spectrometry. Its introduction, together with electrospray ionization in the late 1980s, extended the mass range of molecules that could be examined by mass spectrometry into the low megadalton range and provided a new tool that could be used for analysis of both biopolymers and synthetic polymers. The technique is comparatively simple to use; the sample is mixed with an excess of a suitable matrix, usually

a solid, and ionized with pulses from a laser (**Figure 1**). Ion detection is usually, but not exclusively, achieved by use of a time-of-flight (TOF) mass spectrometer. The purpose of the matrix is mainly to dilute the sample and dissipate the laser energy; however, the details of the ionization process are still poorly understood and subject to intensive research. The technique is capable of high-throughput spectral recording and typical target plates, such as those used for proteomics, can accommodate several hundred samples. Since its introduction, MALDI has become one of the major techniques for ionizing organic molecules and has largely replaced older, less sensitive, methods such as fast-atom bombardment. This article briefly reviews the technique and describes applications to several compound types.

Two variations of MALDI mass spectrometry were invented almost simultaneously in the late 1980s. In

**Figure 1** MALDI ion source.

the version invented by Koichi Tanaka in Japan, a matrix of glycerol and cobalt powder was mixed with the sample and ionized with a laser. In the other version, invented by Michael Karas and Franz Hillenkamp in Germany, and which has enjoyed much more popularity, the sample was co-crystallized with a ultraviolet absorbing matrix, nicotinic acid, and ionized with a frequency-quadrupled Nd-YAG laser. The main products were singly charged ions such as  $[M + H]^+$  or  $[M + Na]^+$  and the technique was shown to be capable of ionizing proteins with masses in excess of 100 kDa.

## Instrumentation

Commercial instruments now almost invariably use nitrogen lasers emitting at 337 nm although several other wavelengths including those in the infrared (IR) region of the spectrum have been used experimentally. As MALDI naturally produces a pulsed ion beam, it is ideally interfaced to TOF mass spectrometers that are ideally suited to record the massive, largely singly charged ions produced in most analyses. The mass range of the technique is usually limited, not by its ability to ionize molecules but by the drop in signal strength with increasing mass imposed by most common mass spectrometric detectors. In reality, the method is useful up to  $\sim 300$  kDa on commercial instruments although ions can sometimes be seen at much higher mass.

Other types of mass spectrometer have been used to record MALDI spectra; magnetic sector instruments equipped with an array detector initially offered the advantage of higher resolution than was available with the early linear TOF instruments but these spectrometers have now largely been replaced with reflectron-TOF instruments using delayed extraction ion sources. Mass spectrometers operated with higher than normal ion source pressures to

provide collisional cooling of the ion beam have recently allowed hybrid quadrupole-TOF (Q-ToF) instruments to record spectra from MALDI ion sources and to produce high-quality fragmentation spectra by collisionally induced decomposition. The recently introduced TOF/TOF instruments have enabled high-energy fragmentation spectra to be obtained; such spectra provide additional information such as the structure of the amino acid side-chain of peptides and linkage position between the sugar rings of complex carbohydrates.

## Matrices

Most types of molecule can be ionized given a suitable matrix and a considerable amount of work has been performed on the determination of the best matrices for various compounds. Many of the most popular matrices are listed in Table 1. Some of these matrices, such as 2,5-dihydroxybenzoic acid (DHB), are suitable for a broad range of compounds whereas others, such as sinapinic acid, tend to work with only a few compound types, such as proteins in the case of sinapinic acid. As the technique has matured, most analyses for a particular compound type will be conducted with only a limited number of matrices.

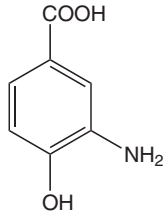

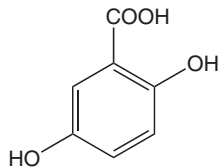

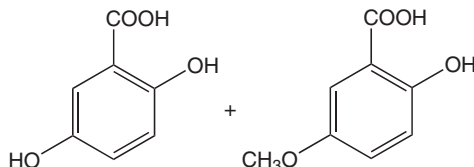

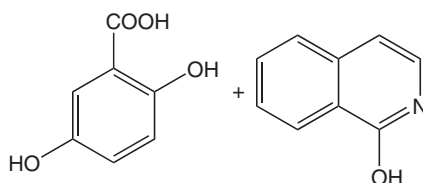

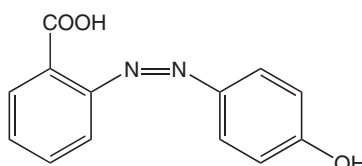

In order to function as a satisfactory matrix, a compound should possess the following properties:

1. The ability to form crystals incorporating the analyte into the crystal lattice or the ability to dissolve the analyte if the matrix is a liquid.
2. The ability to absorb the laser energy.
3. Possess sufficiently poor volatility that sample spots remain on the target in the vacuum system of the mass spectrometer for a reasonable time but, at the same time, be sufficiently volatile that they can be vaporized with the laser.
4. Possess suitable chemistry such that they are able to ionize the sample, usually by proton transfer, but, at the same time, they should not modify the analyte chemically.

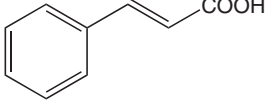

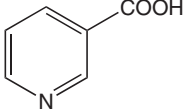

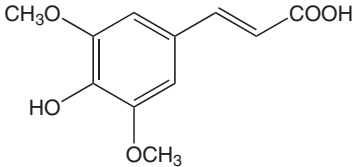

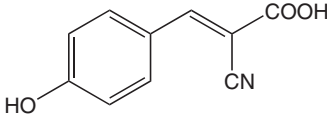

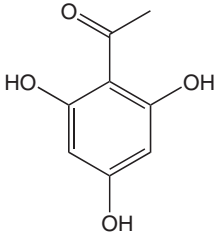

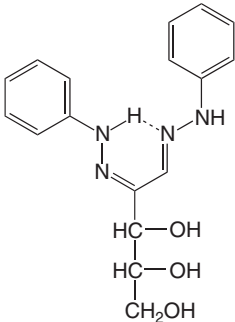

Most of the early matrices were small organic acids capable of protonating the proteins and amino acids that were the main early targets of the technique, but many neutral and even basic compounds are now employed for different compound types.

The most common method for preparing a MALDI target, known as the dried droplet technique, is to mix the sample and matrix, usually in a ratio of about 1:5000 in  $\sim 1$   $\mu$ l of solvent, and allow the mixture to dry on the target. Mixing can occur either before addition to the target or, more commonly, solutions of the sample and matrix are added to the target independently and allowed to mix. Most

**Table 1** Common matrices for MALDI mass spectrometry

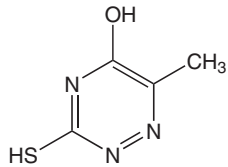

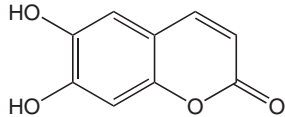

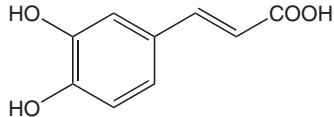

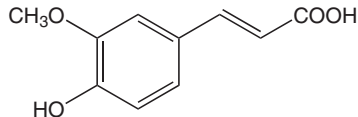

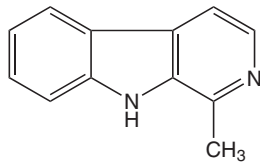

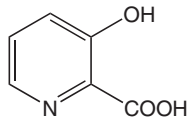

Matrix	Abbreviation	Molecular weight	Solvent	Analyte	Structure
3-Amino-4-hydroxybenzoic acid	–	153.1	MeCN/H <sub>2</sub> O	Sugars	
2,5-Dihydroxybenzoic acid	DHB	154.1	MeCN, acetone	General, particularly sugars

All-trans-retinoic acid	—	300.4	Tetrahydrofuran (THF)	Synthetic polymers	

samples are allowed to dry under ambient conditions but drying is sometimes accelerated by heat, currents of air or nitrogen, or by placing the target in a desiccator.

Although this method works well for the majority of compounds, many variations have been developed to accommodate different analyte properties or simply to improve signal strength or quality. For example, in the layering technique, a film of matrix is deposited on the target in an organic solvent and allowed to dry quickly. The sample solution, with or without additional matrix, is then placed on top and allowed to dry as normal. Sometimes an additional matrix is added at this stage and again allowed to dry. The small matrix crystals from the original layer are thought to catalyze the formation of small crystals in the final target spot, thus producing a more homogeneous target.

Some matrices, such as DHB, produce only a few large crystals, usually originating at the periphery of the target and pointing inwards. Consequently, with instruments that are not fitted with a camera that is able to image the target, it can be difficult to find a suitable spot from which to record a signal. Thus, in addition to the layering technique, several other procedures have been introduced to overcome the problem. One such method, used with carbohydrates, is to recrystallize the sample spot, once dried, with ethanol. This procedure not only reduces the crystal size but is also thought to produce better uptake of the sample by the matrix. Another method is to use a mixed matrix where the added substance, usually in a ratio of about 10:1 sample to additive, forms small seed crystals for the main matrix. Examples are the addition of 2-hydroxy-5-methoxybenzoic acid or 1-hydroxy-*iso*-quinoline (HIQ) to DHB, the former mixture being known as super-DHB. Additives may also be used to form ion pairs with the sample or impurities in the target solution. Ion pairing of sulfated carbohydrates with amino acids (see below) is an example of the first additive whereas the use of citric acid to bind interfering cations in hydroxybenzophenone matrices is an example of the second. L-Fucose has also been used as a matrix adduct to improve spectral quality; it has been proposed that this decomposes to carbon dioxide and water within the laser plume to enhance the number of ion-molecule reactions.

It appears to be important for the sample to enter the crystal lattice of the matrix for satisfactory ion production to occur and proteins tagged with a dye have been used to demonstrate that inclusion does indeed take place. Under ideal conditions high sensitivity can be achieved; some samples can be analyzed from as little as a few hundred attomoles applied

to the target and often, after spectral acquisition, the remaining sample can be recovered. The technique is reasonably sensitive to the presence of contaminants such as salts and buffers but is more tolerant to the presence of these compounds than techniques such as electrospray. A slight drawback to the technique results from the inhomogeneity of the sample surface that causes the signal strength to vary across the target. Consequently, it is sometimes necessary to hunt for so-called sweet spots when acquiring a spectrum. MALDI is a relatively quantitative technique providing that sufficient laser shots are acquired per spectrum to even out the variations in intensity caused by the inhomogeneous target. However, although accuracy can be relatively high, precision is usually only in the order of  $\pm 10\%$ .

Except for some of the larger proteins, MALDI produces almost exclusively singly charged ions. The reason is thought not to be associated with the initial ionization process, but with subsequent reactions in the plume of material desorbed by the laser. It is thought that, as in electrospray ionization, multiply charged ions are initially formed but that these undergo collisions in the plume, predominantly with matrix molecules, allowing neutralization to occur. It has been proposed that such processes are mainly under thermodynamic control, allowing predictions to be made as to the nature of the resulting spectra. Such ion-molecule reactions could explain, for example, why ionization from matrices such as DHB doped with divalent metals such as copper, produce only singly charged ions. Because the second ionization potential of copper (20.29 eV) is above that for DHB (8.05), collisions between ionized copper and DHB result in charge transfer to the matrix. Similar processes are thought to account for phenomena such as matrix suppression and specific analyte ion suppression that are seen under some conditions.

Sample purity is an important factor in obtaining a good MALDI spectrum as contaminants such as salts and buffers tend to inhibit efficient crystallization of sample targets. Among micropurification methods in common use is drop-dialysis in which droplets (about 1  $\mu$ l) of the sample solution are spotted onto a dialysis membrane floating on the surface of water. A variant, used in carbohydrate work, is to use a Nafion-117 membrane that additionally adsorbs hydrophobic compounds. Various ion-exchange resins are in common use; for MALDI work, these are frequently used as microcolumns packed into small pipette tips. Thus, peptides can be efficiently desalted by adsorption onto a C18 solid phase often packed into a pipette tip and sold under the name of ZipTip. Various other such tips including ion-exchange resins have recently become available. Another desalting

technique is to add a few beads of an ion-exchange resin, such as AG-50, to the MALDI target. The beads can either be removed mechanically before introduction of the target into the mass spectrometer, or they can be left on the target with little apparent effect on spectral quality.

## **Variants of the Basic MALDI Technique**

### **Atmospheric Pressure MALDI**

In atmospheric pressure MALDI (ap-MALDI), the sample is ionized outside the vacuum system and ions are captured through a small orifice, usually into an ion-trap mass spectrometer. Its advantage appears to be a considerable amount of rapid collisional cooling of the ions by the high atmospheric pressure, leading to stabilization of sensitive compounds. On the other hand, some compounds, such as carbohydrates, appear to suffer increased fragmentation under these conditions.

### **Surface Enhanced Laser Desorption/Ionization**

Surface enhanced laser desorption/ionization (SELDI) is a variant of MALDI in which the MALDI probe is derivatized with various substances that have affinity for the analyte. The probes are then used to extract the analyte directly from mixtures thus avoiding sample loss through more complicated procedures such as column chromatography. Contaminants can be washed from the probe with appropriate buffers or solvents leaving the purified analyte ready for analysis. Many adsorbents have been used; typical examples are hydrophobic or ionic compounds, enzymes, various receptors, antibodies, and nucleic acids. Although most applications have been reported with proteins, the technique is potentially applicable to any type of compound for which a specific adsorbent can be attached to the probe.

Three types of SELDI are recognized, surface-enhanced affinity capture (SEAC), surface-enhanced neat desorption (SEND), and surface-enhanced photolabile attachment and release (SEPAR). With SEND, the energy-absorbing molecules are bound to the probe surface, often covalently and no additional matrix is necessary. In recent years, porous silica has been found to be an effective SEND surface. Although large molecules can be desorbed, the technique has largely been restricted to small-molecule analysis. Additional binding between the analyte and the energy-absorbing compound is involved with SEPAR and analytes are released photochemically during the ionization process. SEAC is the most widely used SELDI technique; the probe essentially

acts as the purification device via affinity capture and then spectra are recorded, as in classical MALDI, following the addition of an appropriate MALDI matrix. Various affinity probes are now commercially available and the technique offers great potential for examination of trace material in complex biological matrices.

## Applications of MALDI to Specific Compound Types

### Proteins

Proteins produce mainly singly charged ions (Figure 2), usually by protonation and the larger ones are usually ionized from sinapinic acid. However, DHB, ferulic acid, and nicotinic acid can also be effective. A small amount (usually 0.1%) of organic acid, such as trifluoroacetic acid, is often added to aid protonation. In addition to the main singly charged monomeric ions, the resulting spectra usually contain weak doubly charged ions and oligomers, usually dimers and occasionally trimers. For many proteins, these additional oligomeric ion peaks are artifacts of the MALDI process and are more abundant from samples containing high concentrations of protein. However, their observation has prompted research into whether MALDI can be used to study protein-protein interactions. The answer appears to be yes in certain circumstances although, in general, milder techniques such as electrospray, which maintain more realistic physiological conditions, are preferred. Nevertheless, MALDI has been used for measurements of physiologically relevant protein-protein interactions under appropriate conditions. These conditions include proper choice of matrix and pH, the use of chemical cross-linking, or by recording spectra from only one laser shot aimed at any particular region of the target in order to minimize laser-induced dissociation of the complex.

**Figure 2** Typical positive ion MALDI mass spectrum of a protein.

The accuracy of protein mass measurement depends on a number of factors because many proteins are sufficiently massive that resolution is not achieved from additional species such as salts or matrix adducts. Under these conditions, such species cause peak broadening and result in a small shift in measured mass to higher values. Post-translational modifications such as glycosylation can often be resolved for the smaller proteins such as ribonuclease B (Figure 3) with a single glycosylation site, but larger compounds with multiple modifications often produce only broad peaks.

### Peptides

Peptides are usually ionized as  $[M + H]^+$  ions from  $\alpha$ -cyano-4-hydroxycinnamic acid (4-HCCA) or DHB and produce very different molar responses depending on the proton affinity of the constituent amino acids. Arginine-containing peptides, for example, usually produce very strong signals and can be detected at the attomole level. Glycopeptides, on the other hand, frequently give very weak signals in the presence of peptides due to ion suppression phenomena and can ionize as  $[M + H]^+$  and/or  $[M + Na]^+$  species depending on the size of the carbohydrate and the proton affinity of the peptide. A major application of MALDI to peptide analysis is in the area of proteomics where MALDI can provide a very rapid throughput of the resulting tryptic peptides. Unlike electrospray, however, under MALDI conditions, tryptic peptides will produce singly rather than doubly or triply charged ions.

### Carbohydrates

Many matrices have been used for carbohydrate analysis but 2,5-DHB has proved to be the most versatile and widely used. Esculetin is more specific, however, and ionizes sugars in preference to peptides and glycopeptides in mixtures of these compounds (Figure 4). Carbohydrates form  $[M + Na]^+$  ions with most matrices but other adducts can be produced if the matrix is doped with the appropriate salt. Anionic carbohydrates additionally form  $[M - H]^-$  ions. Sensitivity in both modes is lower than with peptides as the latter can be efficiently protonated because of their high proton affinity. However, sensitivity can be increased by permethylation or derivatization at the reducing terminus with a compound that can be protonated, such as a tertiary amine or one that possesses a constitutive charge. Alkyltrimethylammonium compounds have been used in the latter context.

Mixtures of polymeric carbohydrates, such as dextrans, tend to show a drop in sensitivity for the

**Figure 3** Positive ion MALDI mass spectrum of ribonuclease B, a glycoprotein with a single *N*-linked glycosylation site.

**Figure 4** Positive ion MALDI mass spectrum of *N*-linked glycans released from ribonuclease B and recorded from (A) 2,5-DHB and (B) esculetin.

larger molecules such as those with masses  $\sim 10$  kDa (Figure 5) but signals can be increased by removal of the shorter polymers by size-exclusion chromatography. For smaller compounds such as

*N*-linked glycans, ionization appears reasonably consistent over the mass range of 2–3 kDa that most of these compounds fall into but smaller O-linked glycans suffer a drop in sensitivity and interference

**Figure 5** Positive ion MALDI mass spectrum of glucose oligomers recorded from 2,5-DHB.

by ions from the matrix. The consistent ionization shown by glycans of similar mass is related to the ionization being produced by sodium adduction rather than protonation, a mechanism that is similar for all compounds. Sialylated glycans are unstable under MALDI conditions and eliminate substantial amounts of sialic acid with the result that broad metastable ions appear in spectra recorded with reflectron-TOF instruments. Methylation or salt formation can stabilize the sialic acids by removing the labile acidic proton that is involved in the sialic acid loss. Sulfated glycans, such as glycosaminoglycans, eliminate sulfate but can be examined by ion pairing with a suitable amino acid such as (RG)<sub>15</sub>.

### Nucleic Acids

Small oligonucleotides with four to six base pairs were first analyzed by MALDI mass spectrometry in 1990 but it was soon clear that oligonucleotide analysis by this technique was beset by two problems: salt formation and fragmentation. Salts were the result of the affinity of the phosphate groups for alkali metals whereas fragmentation appeared to be related to protonation of the base. Salt formation can be reduced by use of ammonium salts, either added to the matrix or exchanged into the sample before target preparation. The ammonium ion transfers a proton to the phosphate to create the free acid by dissociation of the ammonium phosphate ion pairs following desorption. Fragmentation can be reduced by chemical modification. Thus, 7-diaza-analogs of purine groups confer stability whereas adenine and guanine bases can be stabilized by replacement of the 7-nitrogen group with carbon.

Like other compounds, successful analysis of oligonucleotides depends on selection of a suitable matrix. An early system used frozen aqueous solutions on a copper target with irradiation with visible light at 581 nm. DNA with more than 600 bases could be desorbed intact. However, molecules with over 2000 nucleotides have been detected using IR-MALDI. Possibly the most useful matrix for oligonucleotides is 3-hydroxypicolinic acid (HPA). It produces both positive and negative ions although better results have been reported for the negative ion spectra. The addition of a polyamine comatrix such as spermine has been reported to improve spectral quality.

Double-stranded DNA becomes denatured under MALDI conditions with only ions corresponding to the monomer chains appearing in the spectra. Sensitivity appears to be a function of base composition. Thus, homopolymers containing thymine yield stronger signals than homopolymers containing the other three bases. The reason is thought to be related to fragmentation rather than absorption into the MALDI crystal lattice as thymine is more difficult to protonate than the other bases. Reduced fragmentation has been proposed as the reason why RNA produces stronger signals than DNA; the presence of the 2'-hydroxy group prevents the occurrence of the proposed 1',2'-*trans*-elimination involved in glycosidic cleavage of the ribose moiety from the base.

### Lipids

Analysis of lipids by MALDI mass spectrometry has received much less attention than analysis of proteins and peptides but lipids can, nevertheless, be induced to produce strong signals with suitable matrices.

**Figure 6** Positive ion MALDI mass spectrum of polyethylene glycols recorded from 2,5-DHB.

Phospholipids can be ionized from the popular matrices such as DHB or 4-HCCA but positive ion signal strengths vary considerably with the different types of lipid; phosphatidylcholine, with its quaternary nitrogen atom, produces very strong positive ion signals whereas phospholipids such as phosphatidylinositol, which do not possess a positive charge or amine group, are more difficult to ionize and produce weaker signals. Glycosphingolipids generally behave as derivatized carbohydrates and ionize well from DHB with the production of  $[M + Na]^+$  ions. However, deacylation as with lyso-sphingolipids, converts the amide group into an amine with the result that both  $[M + H]^+$  and  $[M + Na]^+$  ions are formed. MALDI is used extensively in the analysis of bacterial glycolipids such as lipid A, usually in negative ion mode, because of the presence of phosphate or other acidic groups.

### Synthetic Polymers

A considerable amount of work has been reported on the use of MALDI mass spectrometry to examine synthetic polymers. The most popular matrices are DHB, HABA, 1,8,9-trihydroxyanthracene (dithranol), and all-*trans*-retinoic acid, doped with a cationization reagent such as copper or silver. The oligomer distribution, the composition of the end groups, the repeat unit, and the nature of any chemical modifications can all be determined if oligomer

resolution can be attained but one of the major applications is in measurement of the mean molecular weight of polydisperse fractions (Figure 6).

The main problem with analyses of this type is mass discrimination against the larger compounds, caused both by instrumental and matrix factors. Instrumental factors are usually the result of detector saturation as most detectors do not have the dynamic range necessary to accommodate the concentration differences between the various constituents of the polymer mixture. Solvents also have a marked effect on the accuracy of the results. As most synthetic polymers are insoluble in aqueous solvents, the presence of water can have an adverse effect on crystallization. In mixtures containing water, if the organic solvent is more volatile it will evaporate first, causing precipitation of the polymer and inefficient incorporation into the matrix. Nevertheless, for mixtures covering a relatively narrow mass range, MALDI can give an accurate value for the average molecular weight.

### Introduction

A mass spectrometer can be broken down into four basic components: sample introduction, ionization, mass separation, and detection/recording. This article will concentrate on mass separation, or ‘analysis’, although the components should not be treated in complete isolation as there are interactions between them.

The modes of mass analysis that will be considered here can be classified as follows:

- Continuous mode:
  - magnetic sectors, possibly with electric sectors
  - quadrupole mass filters
- Pulsed mode:
  - time-of-flight (TOF) analyzers
- Ion trapping devices:
  - quadrupole traps
  - Fourier-transform ion cyclotron resonance traps.

These various methods differ widely in cost, size, and complexity, and also in terms of performance (i.e., mass/charge range and resolving power). The

preferred method of mass analysis depends on the type of problem being investigated.

### Types of Mass Analyzer

#### Magnetic Sectors

Magnetic sector instruments are relatively expensive but they generally give high performance when combined with electric sectors, especially in terms of resolution, mass measurement accuracy, sensitivity, and  $m/z$  range. They employ high accelerating potentials (several kilovolts) in comparison with quadrupole instruments. An ion of mass  $m$  and charge  $ze$  accelerated out of an ion source through potential  $V$  will acquire a velocity  $v$ , and under the influence of a magnetic field of intensity  $B$  will follow a circular path of radius  $r$ . The following equations apply:

$$\text{Ion kinetic energy: } mv^2/2 = zeV \quad [1]$$

$$\begin{aligned} \text{Deflecting force: } BzeV &= \text{centrifugal force} \\ &= mv^2/r \end{aligned} \quad [2]$$

$$\text{Combining these: } m/z = B^2 r^2 e/2V \quad [3]$$

The number of charges,  $z$ , is usually equal to one, so eqn [3] shows that a spectrum of masses can be obtained by changing one of the three variables,  $B$ ,  $r$ ,

### Introduction

A mass spectrometer can be broken down into four basic components: sample introduction, ionization, mass separation, and detection/recording. This article will concentrate on mass separation, or ‘analysis’, although the components should not be treated in complete isolation as there are interactions between them.

The modes of mass analysis that will be considered here can be classified as follows:

- Continuous mode:
  - magnetic sectors, possibly with electric sectors
  - quadrupole mass filters
- Pulsed mode:
  - time-of-flight (TOF) analyzers
- Ion trapping devices:
  - quadrupole traps
  - Fourier-transform ion cyclotron resonance traps.

These various methods differ widely in cost, size, and complexity, and also in terms of performance (i.e., mass/charge range and resolving power). The

preferred method of mass analysis depends on the type of problem being investigated.

### Types of Mass Analyzer

#### Magnetic Sectors

Magnetic sector instruments are relatively expensive but they generally give high performance when combined with electric sectors, especially in terms of resolution, mass measurement accuracy, sensitivity, and  $m/z$  range. They employ high accelerating potentials (several kilovolts) in comparison with quadrupole instruments. An ion of mass  $m$  and charge  $ze$  accelerated out of an ion source through potential  $V$  will acquire a velocity  $v$ , and under the influence of a magnetic field of intensity  $B$  will follow a circular path of radius  $r$ . The following equations apply:

$$\text{Ion kinetic energy: } mv^2/2 = zeV \quad [1]$$

$$\begin{aligned} \text{Deflecting force: } BzeV &= \text{centrifugal force} \\ &= mv^2/r \end{aligned} \quad [2]$$

$$\text{Combining these: } m/z = B^2 r^2 e/2V \quad [3]$$

The number of charges,  $z$ , is usually equal to one, so eqn [3] shows that a spectrum of masses can be obtained by changing one of the three variables,  $B$ ,  $r$ ,

**Figure 1** The variables for separation by a magnetic analyzer.

or  $V$ , as illustrated in **Figure 1**. Commercial instruments have been produced for each of these modes of scanning:

- **Magnetic scanning,  $B$ :** Most commonly used; provides wide mass range without loss of performance at high mass, as in the case of voltage scanning (see below). The disadvantages of hysteresis and slow scanning associated with electromagnets have largely been overcome with modern laminated and/or air core magnet designs.
- **Change of radius,  $r$ :** Not possible with a fixed detector, although special applications such as accurate isotope ratio measurements use two or more fixed detectors. This method was used historically with photoplate detection, and has been revived with microchannel plate photodiode array detectors; this can improve signal-to-noise ratio as all the ions of interest can be monitored simultaneously and hence continuously.
- **Voltage scanning,  $V$ :** No theoretical limit to the mass range as the mass is inversely proportional to the accelerating potential. However, in practice the extraction efficiency of ions from the source depends on  $V$ ; in addition, the ions rely on the kinetic energy imparted by the potential for effective transmission through the instrument, and hence the performance deteriorates at high mass. Advantages are the relatively low cost of permanent magnets (which do not, of course, require electronic circuits), fast scanning, and the reproducibility of the scan function as there is no hysteresis.

Many commercial instruments combine different scan modes, for example, using an electromagnet for normal scanning ( $B$ ), and voltage scanning ( $V$ ) for rapid, reproducible single peak display or multiple peak monitoring. High-performance magnetic scanning instruments are available with array detectors for increased sensitivity of detection over a restricted mass range ( $r$ ).

Dividing eqn [2] by  $v$  shows that a magnetic sector is not a true mass analyzer as the radius of the ion

**Figure 2** The focusing properties of a magnetic sector.

path actually depends on the product of mass and velocity  $mv$  (momentum). Ions of a common mass accelerated through the same potential  $V$  should all have the same momentum, but in practice this will not be entirely true and a single-focusing magnetic sector instrument will give a broadened image at the collector slit, thereby reducing the resolution. Another potential source of loss of resolution is the angular broadening of the beam as it enters the magnetic field. A wedge-shaped magnet has a focusing action, and as long as the source slit and collector slit are on a line passing through the center of the circle where the ion path through the magnet is an arc, a divergent beam will be focused at the collector slit. The field must be homogeneous and the ion beam must enter and leave the magnet at  $90^\circ$ . Angular and energy focusing are illustrated in **Figure 2**.

### Double Focusing Magnetic Sector Instruments

Ions can also be deflected by electric fields, although an electric sector has properties different from a magnetic sector, deflection being dependent upon the kinetic energy of the ions rather than the momentum, i.e., independent of mass. This is described by eqn [4] for an electric field of strength  $E$ :

$$\text{Deflecting force } zeE = \text{centrifugal force} = mv^2/r \quad [4]$$

Therefore, the electric field can be used as a focusing element but does not need to be scanned to pass the full range of masses. **Figure 3** shows the double focusing effect of a combination of a magnetic sector and an electric sector for a beam of ions of common mass but being both angularly and energetically divergent. This example has 'reversed' geometry in that the magnet comes before the electric sector, and is the reverse of the original design by Nier and Johnson. This does not affect the focusing properties. Ions with higher kinetic energy are deflected less than

**Figure 3** Double focusing mass spectrometer.

those with lower kinetic energy, so that although the angularly divergent beams are brought to focus at the  $\beta$ -slit (which is equivalent to the collector slit in a single-focusing instrument), the spread of energies has broadened the beam and it cannot pass through a narrow slit without loss of sensitivity. Thus, the  $\beta$ -slit is usually quite wide for maximum transmission. In the electric sector the higher energy ions take a longer path through the electric field and they are deflected more than the lower energy ions, thereby bringing the energetically divergent ions back to a focus at the collector slit.

The geometry of the instrument is accurately calculated so that the angular and energy foci coincide at the collector slit, hence the name double focusing. The design affords a means of compensating for the spread of kinetic energies in the ion beam and allows high mass resolution to be attained by using narrow source and collector slits. The resolving power required to separate a peak due to ions of mass  $M$  from a peak of mass  $M + \Delta M$  is defined as  $M/\Delta M$ . If these peaks differ in mass by one part in 60 000, the resolving power needed will be 60 000, which is the sort of performance that can be attained from a large modern double focusing instrument. Two peaks of equal height are defined as being resolved when the valley between them does not exceed 10% of the peak height (10% valley definition), which for symmetrical peaks corresponds to defining the resolution relative to the peak width at 5% of the height. This is illustrated in **Figure 4**. There are other definitions that include 50% peak height, i.e., full-width at half-maximum. For a sector instrument the resolving power  $M/\Delta M$  is constant throughout the mass range, but the ability to separate peaks that differ by a constant amount deteriorates at high mass, e.g., an instrument of resolving power 1000 can separate peaks differing in mass by less than 1 Da up to mass 1000, but at mass 10 000 it can only separate peaks differing by 10 Da.

**Figure 4** Ten percent valley definition of resolving power.

A high-resolution mass spectrometer allows the accurate determination of ionic masses to within  $\sim 1$  ppm. The mass defects in the atoms that make up organic molecules allow the atomic composition to be determined from the accurate mass, e.g., ions at  $m/z$  28 can be  $\text{CO}^+$  (27.994914),  $\text{N}_2^+$  (28.006148),  $\text{CH}_2\text{N}^+$  (28.018724), or  $\text{C}_2\text{H}_4^+$  (28.031300). This works well up to  $\sim m/z$  500, above which point the decreasing accuracy of mass measurement (as explained above) and the increasing number of possible compositions at each mass make the technique less useful.

The choice of forward or reversed geometry for a double focusing mass spectrometer is not important for the attainment of high resolution. However, there can be other reasons for adopting a particular configuration, especially for studies of metastable ions and tandem mass spectrometry. Ions that are accelerated out of the ion source by field potential  $V$  all have essentially the same kinetic energy and are transmitted by the electric sector at its 'normal' strength. However, ions that fragment in the flight tube lose a fraction of their kinetic energy, which is partitioned between the new ion and neutral fragment, and they can only pass through the electric sector at a reduced field strength. Metastable ions breaking down in the second field-free region between the two sectors will be transmitted by the magnet in a forward geometry instrument, although at reduced magnetic field, to give the familiar broad and rather weak metastable peaks in the normal mass spectra. In a reversed geometry instrument the electric sector will act as a barrier to these ions, which will not have sufficient energy for transmission. Consequently, the normal mass spectra show no metastable peaks.

However, by reducing the electric field the 'normal' ions can be discriminated against and only the ionic products from the metastable fragmentations will be transmitted, giving pure metastable spectra. For both geometries it is possible to scan both sectors simultaneously in a 'linked scan', which provides low-resolution tandem mass spectrometry.

### Time-of-Flight Analyzers

TOF analyzers have recently enjoyed a considerable resurgence with the introduction of desorption ionization techniques such as laser desorption.

In the original design shown in **Figure 5**, the ions are formed in an electron impact source in which the electron beam is pulsed by applying a square wave voltage to a control grid. The acceleration of the ions into the flight tube is similarly pulsed, so that ions are introduced into the mass analyzer in bursts. The accelerating potential of  $\sim 3$  kV gives all the ions the same kinetic energy:

$$zeV = mv^2/2 \quad [5]$$

thus

$$m/z \propto 1/V^2 \propto t^2 \quad [6]$$

The ions travel down a 1 m linear drift tube and are separated according to mass, the lighter ions reaching the collector before the heavier ones, and the masses being calculated from the flight times. The output, which is stored in a fast digitizer and sent onto the control computer for display, can respond extremely rapidly to changes in the sample composition as a spectrum can be recorded in milliseconds.

The major problem with early designs was associated with poor resolution, arising from the length of the gating pulses and the spread of kinetic energies due to thermal energies and local differences in the accelerating field. The maximum resolving power was  $\sim 140$ , which in turn restricted the useful mass range although in theory the mass range of a TOF instrument is infinite.

More recently, the unrestricted mass range has been exploited in matrix-assisted laser desorption TOF mass spectrometers for protein analysis at masses up to 1 000 000 Da. Improvements in resolving power have come from several developments:

1. Modern electronics provide much greater accuracy in gating and timing, so that flight times can be recorded with nanosecond precision.

**Figure 5** TOF mass spectrometer.

2. The pulsed nature of ion formation using techniques such as laser desorption, whereby all ions are formed in a very short space of time and can therefore start their flight through the drift tube simultaneously. This has been further enhanced by the use of a gating voltage to delay the ion extraction and has given rise to the current high resolution (up to 20 000) for modern TOF instruments.

3. The development of reflectron instruments to compensate for differences in kinetic energies. This is illustrated in **Figure 6**, and shows the ions penetrating into an electric field and being repelled or reflected back out again. The higher energy ions penetrate further into the field before being reflected, and therefore follow longer path lengths requiring longer times. This compensates for the shorter time they spend traversing the field-free region, and so eliminates the broadening associated with the spread of kinetic energies, leading to time-focusing.

With these improvements it is possible to obtain resolving powers of 20 000 with TOF instruments, comparable to the performance of sector instruments.

### Quadrupole Analyzers

Quadrupole mass spectrometers are generally less-expensive, lower-performance instruments, not capable of high resolution, but they offer the advantages of flexibility, simplicity, ease of interfacing to liquid chromatography and gas chromatography (as they do not use high potentials in the ion source), ease of computer interfacing and mass calibration (as they have a linear scan law), and speed of scanning and stepping between peaks for multiple ion monitoring. As explained above, the magnetic sector is actually a momentum analyzer and the electric sector is a kinetic energy analyzer, although both can give mass analysis under certain conditions. However, the quadrupole analyzer is a true mass analyzer as it is unaffected by changes in ion velocity, i.e., in momentum or kinetic energy.

**Figure 7** shows the quadrupole analyzer, which consists of four parallel rods, the surfaces of which should actually be hyperbolic, but circular rods are

**Figure 6** The reflectron TOF mass spectrometer.

**Figure 7** The quadrupole analyzer.

**Figure 8** Ac and dc voltages.

easier to manufacture and give satisfactory performance. The rods are electrically connected in diagonally opposite pairs and mass separation is achieved by applying a dc potential  $+U$  to one pair ( $x$ ) and  $-U$  to the other ( $y$ ), and superimposing a radio-frequency ac potential  $V \cos \omega t$ , which differs in phase by  $180^\circ$  between the pairs of rods. The peak value of the ac voltage is greater than the dc voltage, so the 'positive' pairs are sometimes negative, and vice versa, as shown in **Figure 8**.

Low kinetic energy ions ( $\sim 20$  eV) are introduced and under the influence of the oscillating field follow a spiral path through the analyzer between the rods (along the  $z$ -axis). Their motion on the  $x$  and  $y$  axes is defined by the Mathieu equations, which are of the form shown below for  $x$  (eqn [7]), with an identical equation for  $y$ :

$$\frac{d^2x}{d(\omega t/2)^2} + (a + 2q \cos \omega t)x = 0 \quad [7]$$

**Figure 9** Stability diagram for quadrupole analyzer.

The terms  $a$  and  $q$  are defined as follows:

$$a = 8eU/mr^2\omega^2 \quad [8]$$

and

$$q = 4eV/mr^2\omega^2 \quad [9]$$

where  $r$  is the radius from rod surface to center line; thus,

$$a/q = 2U/V \quad [10]$$

If the ac frequency is kept constant,  $m$  is linearly proportional to  $U$  and  $V$ . In scanning the instrument the ratio  $a/q$  is kept constant by maintaining a fixed ratio between  $U$  and  $V$  (eqn [10]), which are scanned simultaneously to give a spectrum that is linear in mass. The behavior of the ions is defined by the stability diagram shown in **Figure 9**.

Within the shaded triangle the ions follow stable orbits and they are transmitted through the analyzer, whereas outside this triangle the orbits become infinitely large and the ions are lost. The gradient of the scan line determines the proportion of ions transmitted. If  $U = 0$ , i.e., no dc voltage, all ions will pass through and there will be no mass separation. As the gradient of the scan line is increased, i.e., as  $U$  is increased relative to  $V$ , the proportion of ions following stable orbits decreases and the mass resolution increases. If the scan line is too steep it will not intersect with the triangle at all and no ions will be transmitted. The gradient  $a/q$  is therefore selected to cut the shaded triangle near its apex and give the optimum combination of transmission and mass resolution.

The performance of the quadrupole cannot be defined by the  $M/\Delta M$  relationship that applies to sectors, for which the actual peak width increases linearly with mass. With a quadrupole the peak width is constant throughout the mass range, and if the instrument is set up to resolve adjacent mass numbers it is described as having unit resolution. Modern research grade instruments are now available with resolutions up to 5000.

Quadrupoles offer very fast scanning limited only by the impedance involved in changing electric potentials, and are therefore ideally suited to interfacing with high-resolution chromatographic techniques. A typical high-performance quadrupole will have rods of 1 cm diameter and 25 cm in length, possibly preceded by an ac-only quadrupole prefilter. The ac voltage will be in the megahertz frequency range and will have a maximum peak-peak voltage of 10 kV or more.

A quadrupole mass analyzer will not transmit the ionic products of metastable ions breaking down in the analyzer as the change in mass causes the ion orbits to become unstable. However, as explained above, an ac-only quadrupole gives no mass selection and therefore will transmit such ions, and furthermore will do so with high efficiency as the quadrupole is insensitive to ion kinetic energy and is relatively unaffected by angular distribution. Consequently, an instrument known as the triple quadrupole with three quadrupoles in series is routinely used in tandem mass spectrometry. The first and third quadrupoles are mass selective, whereas the second quadrupole is ac-only and is contained within a collision chamber to encourage fragmentation. Quadrupoles can be combined with several other types of analyzers in 'hybrid' instruments.

### Quadrupole Ion Traps

These are essentially a three-dimensional quadrupole in that ions move in the  $x$  and  $y$  directions but there is no  $z$  direction, i.e., the ions oscillate around a fixed point (**Figure 10**). This is a device for storing ions and has been called the QUISTOR (quadrupole ion storage trap). It is constructed from a doughnut-shaped ring electrode with two end-caps, all having cylindrically symmetric hyperbolic surfaces. A radio frequency ac voltage of  $\sim 1$  kV at 1.1 MHz is applied to the ring electrode, which induces the oscillatory motion of the ions. The equations presented for the quadrupole analyzer also apply here, and in the ac-only mode there is no mass discrimination.

Ions can be formed by a variety of techniques either externally in an ion source or directly within the trap.

**Figure 10** The quadrupole ion storage trap (QUISTOR).

Ions flow into the trap controlled by the gating electrode. In the trap, there are stability criteria for the ion trajectories in a manner analogous to the quadrupole, and the application of the ac signal stores ions of all masses down to a low cut-off value of  $m/z$ . Increasing the ac voltage causes the ion trajectories to increase and to approach the end-caps. As this voltage is scanned upwards the ions are ejected from the trap in order of increasing  $m/z$ , and those that emerge through apertures in the lower end-cap are detected by the electron multiplier. Helium is used as a buffer gas in the trap at about  $10^{-3}$  Torr to dampen out the more violent motions and to give improved spectral stability. The storage time can be increased by delaying the start of the voltage ramp.

This allows ion/molecule reactions to occur and may be used to effect chemical ionization (CI). The circular electrode has an inner diameter of  $\sim 2$  cm, and the whole device is compact and inexpensive compared with most analyzers. It is ideal as a low-cost mass-selective detector for chromatography. More sophisticated versions are available for which other scan regimes allow different modes of operation for tandem and other studies including MS<sup>n</sup>.

### Fourier-Transform Ion Cyclotron Resonance Mass Spectrometers

Ion cyclotron resonance (ICR) mass spectrometers have become increasingly popular with the use of Fourier transform (FT) techniques, the development of superconducting magnets, and the importance of pulsed desorption ionization methods and are now in the forefront of mass spectrometer development.

The mass analyzer in an Fourier-transform ion cyclotron resonance (FT-ICR) (or Fourier-transform mass spectrometer (FTMS) instrument is illustrated in **Figure 11**. In its simplest form it consists of a cubic cell made up of six isolated plates,  $2.5 \text{ cm}^2$ , contained in a homogenous magnetic field generated by a superconducting magnet. Sample gas molecules may be ionized within the cell by pulsed electron bombardment, or ions may be formed in a second adjacent cell or more remotely in a separate ionization region and then injected into the analyzer. A small potential applied to two opposite plates (trapping plates) parallel to the axis of the magnetic field traps the ions within the field. Any thermal energy they have will cause them to spiral close to the center of the cube with cyclotron frequencies  $\omega_c$  and velocities  $v$  inversely proportional to  $m/z$ :

$$\omega_c = v/r = zeb/m \quad [11]$$

**Figure 11** Fourier-transform mass analyzer.

The cyclotron frequencies range from megahertz down to kilohertz. The application of a burst of low-amplitude radio frequency power to the side plates (excitation plates) will excite the ions into larger orbits. They will now pass close to the top and bottom plates (receiver plates), and so will induce an electrical signal in the circuit connecting these plates. This signal is amplified, digitized, and stored in a computer for subsequent processing. This involves an analysis of the constituent frequencies of the complex waveform that arises from having a complete range of  $m/z$  values, and is carried out by Fourier transformation. From this the mass spectrum is derived; a key feature of this means of detection is that, unlike all other mass spectrometers, it is nondestructive. The instrument can be operated in a number of different modes. The excited ions will gradually lose kinetic energy and will fall back toward the center of the cell. They can be ejected (quenched) by applying a voltage pulse to the trapping plates before new ions are produced, or they can be re-excited to produce a new signal that allows spectrum averaging in order to obtain an enhanced signal-to-noise ratio. Alternatively, by application of only certain frequencies, some ions can be excited to such large orbits that they strike the sides of the cube and are destroyed. This will leave only selected ions for further study, e.g., in tandem mass spectrometry experiments. It is possible to vary the time between ion formation and excitation for CI or to study the kinetics of unimolecular fragmentation or ion/molecule reactions.

FTMS instruments can operate at very high resolving power, and if the residual pressure is low and the density of ions within the cell is small, the measurement of the cyclotron frequency can be very precise. This allows very accurate measurement of  $m/z$  and very precise separation of adjacent peaks. In a 4.7 T magnetic field at  $10^{-8}$  Pa, the time domain signal measured for  $m/z$  18 over 51 s has been recorded to give a resolving power of  $M/\Delta M = 100\,000\,000$ .

In FTMS, the cell can contain both positive and negative ions simultaneously, and  $\text{Cl}^+$  can be resolved from  $\text{Cl}^-$ , a difference of two electrons ( $\sim 0.001$  Da). Resolving power for the FTMS is inversely proportional to mass, and so is lower for high mass ions.

The mass range for FTMS instruments depends on the strength of the magnetic field, and with large superconducting magnets 10 000 Da for singly charged ions is well within reach; in this respect performance is comparable to large sector instruments. The dynamic range is poor compared with sector instruments as there is a space-charge limit to the number of ions that can be stored simultaneously, i.e., ions repel each other and are lost. The dynamic range achievable with a sector instrument can be greater than  $10^6:1$ , whereas FTMS gives only  $10^3:1$ . The pressure in the FTMS cell must remain low as ions will collide with residual gas molecules, leading to a randomization of their motion. This limits the ionization methods available unless the ions are prepared remotely and injected into the cell.

### Introduction

Wolfgang Paul and co-workers at the University of Bonn, Germany, obtained a patent in the 1950s for a quadrupole mass filter that is the most common analytical mass spectrometer in use today. A mass filter consists of a square parallel array of four round (rather than the ideal hyperbolic form) rods to which a radiofrequency (rf) potential is applied such that opposite rods are held at the same potential and adjacent rods are out-of-phase by  $180^\circ$  (Figure 1). The mass filter is a two-dimensional quadrupole device because there is a quadrupole ion trapping field in the  $x$ - and  $y$ -directions only. Described in the same patent as the mass filter was its three-dimensional (3D) analog, the 3D quadrupole ion trap, wherein three quadrupole fields act. The quadrupole ion trap is an enormously versatile mass spectrometer that is capable of multiple stages of mass selectivity (tandem mass spectrometry, MS/MS and MS<sup>n</sup>), high sensitivity, high mass resolution, and high mass range. In combination with electrospray ionization, the quadrupole ion trap is applied widely for the study of polar molecules such as peptides and proteins.

In recent years, there has been relatively little further development of the quadrupole ion trap; rather, the range of applications has expanded by making use of the versatility of the instrument. Bruker Daltonik has reported recently on a high charge ion trap wherein the hyperbolic angle of the ion trap has been modified. This change in geometry, combined with resonant ion ejection under the influence of combined dipolar, hexapolar, and octopolar fields, permits rapid mass scanning at high mass resolution

of a greater ion charge in the absence of space charge perturbation.

### Theory

The mathematics of ion trajectory stability within a quadrupole field follows the Mathieu second-order differential equation:

$$\frac{d^2 u}{d\xi^2} + (a_u - 2q_u \cos 2\xi)u = 0, \quad \xi = \frac{\Omega t}{2} \quad [1]$$

where the subscript  $u$  refers to ion motion in the  $x$ ,  $y$ , and  $z$  coordinates,  $\xi$  is a dimensionless quantity,  $\Omega$  is the radial frequency of the rf potential, and  $t$  is time. A great strength of quadrupolar devices is that the quadrupole fields are independent of one another. Thus, we can apply solutions of the Mathieu equation to 2D or 3D devices provided the weighting factors in each dimension sum to zero. For a 2D device, the trapping parameters are given as

$$a_x = -a_y = \frac{8eU}{mr_0^2\Omega^2}; \quad q_x = -q_y = -\frac{4eV_{0-p}}{mr_0^2\Omega^2} \quad [2]$$

where  $U$  is a dc voltage,  $V_{0-p}$  is the zero-to-peak amplitude of the rf potential,  $m$  is the ion mass,  $e$  is the electronic charge, and  $r_0$  is the radius of the inscribed circle of the rod array.

### New Types of Ion Traps

In the operation of 2D and 3D quadrupole instruments, the modification of ion trajectories by ion/neutral collisions must be considered. In rf quadrupole fields, an ion/neutral collision reduces both ion kinetic energy and ion excursions such that the ions are cooled and focused to the center of each field. Collisional cooling is an important aspect of the behavior of ions in a quadrupole field; for example, in a 2D quadrupole device, collisional cooling is employed to limit the excursions of ions so as to form a tightly focused ion beam of diminished kinetic energy constrained close to the central axis. A focused beam of ions may be transmitted through a relatively small orifice from one section of an instrument to the next such that pumping requirements are reduced, and a focused ion beam can be accelerated with reduced ion loss. When the axial motion of a focused ion beam is arrested within a rod array such that the confined ions can be excited resonantly, a linear ion quadrupole trap is obtained.

**Figure 1** An ensemble of circular rods that forms a quadrupole mass filter.

There has been substantial development of miniature cylindrical ion traps in response to the demands for a small mass spectrometer for use in the field. The remainder of this article is given over to discussion of novel linear ion traps and miniature cylindrical ion traps that employ quadrupole ion trapping fields.

### Linear Quadrupole Ion Trap Mass Spectrometer

In 2002, two linear ion traps were reported; they had the basic structure of a quadrupole mass filter. The first linear ion trap instrument was described by J.W. Hager of MDS SCIEX and a second linear ion trap instrument was described by J.C. Schwartz, M.W. Senko, and J.E.P. Syka of Thermo Finnigan. Both instruments employ mass-selective ion ejection. Axial ion ejection is employed in the SCIEX instrument while in the Thermo Finnigan instrument ion ejection occurs radially. In addition, ion trapping in the SCIEX instrument can occur either in a pressurized collision cell region or in a low-pressure quadrupole rod array downstream of the collision cell.

The principal advantage of a linear ion trap is that more ions can be confined in the larger device than in a 3D ion trap. Thus, the onset of space-charge repulsion is experienced only at greater ion loading of the trapping device. Virtually all of the operating characteristics of the 3D ion trap are retained in the linear device. Both linear ion trap instruments were developed using existing experimental platforms that permitted prior collisional cooling of the ion beam.

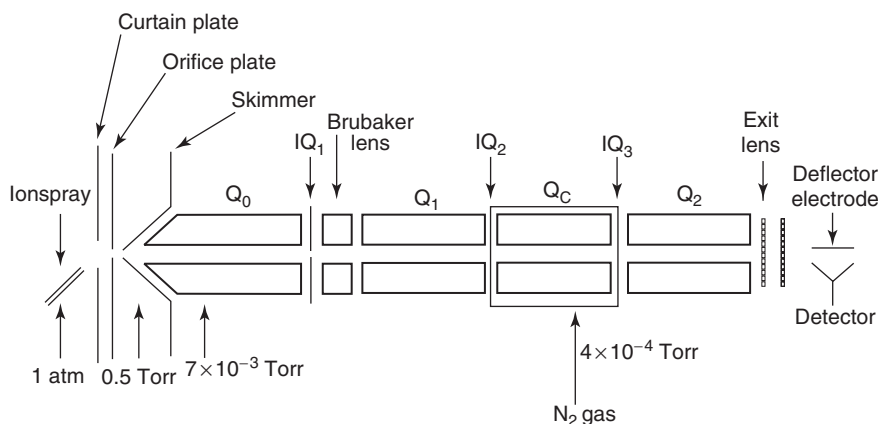

**SCIEX linear ion trap** The SCIEX instrument shown schematically in Figure 2 is based on a triple-stage quadrupole (TSQ) mass spectrometer wherein, normally, the ion beam travels from left to right. Ions

are focused collisionally close to the axis in  $Q_0$ , mass selected in  $Q_1$ , and collisionally dissociated to fragment ions in the collision cell  $Q_C$ .  $Q_C$  is a quadrupolar array of round rods of length 127 mm enclosed in a pressurized container to which a collision gas is introduced.  $Q_2$  is a quadrupole mass filter that has rods of length 127 mm also. The round rod arrays were fabricated with a field radius,  $r_o$ , of 4.17 mm.

When  $Q_C$  or  $Q_2$  is operated as a linear ion trap, an rf drive voltage of 1 MHz is applied. An auxiliary ac potential is applied in quadrupolar fashion to the rod arrays of either  $Q_C$  or  $Q_2$  so as to excite ions at secular frequencies. Ions are trapped radially in the linear ion trap  $Q_C$  by the rf potential, and are confined axially within the rod array by dc potentials applied to the aperture plates,  $IQ_2$  and  $IQ_3$ . Thus, a linear ion trap resembles a bathtub having a parabolic cross-section and near vertical ends. Ions enter the linear ion trap close to the zero-field centerline of the device and encounter a series of momentum-dissipating collisions with collision gas.

When an auxiliary ac field is applied to induce radial resonant excitation, coupling of radial and axial motions effected axial ion ejection when the ion radial secular frequency matched that of the ac field.

**Thermo Finnigan linear ion trap** In the Thermo Finnigan instrument shown in Figure 3, an ion beam from an electrospray source is directed through a heated capillary, two successive rod arrays, a front lens, and into a linear ion trap composed of three sections of quadrupole hyperbolic rod arrays with  $r_o = 4$  mm. Radial confinement of ions is effected by the trapping potential well in the center section and axial confinement by dc potentials applied to the front and rear lenses. The basic design of the linear

**Figure 2** A schematic diagram of the SCIEX linear ion trap mass spectrometer. Ion trapping can be wrought in either of  $Q_C$  or  $Q_3$ . The apparatus is based on the ion path in a TSQ mass spectrometer and the ion beam travels from left to right. Typical operating pressures are given. **Figure 4** An angled view of the three sections of the two-dimensional linear ion trap. The detector faces the center section. (Reproduced with permission from Elsevier from Schwartz JC, Senko MW, and Syka JEP (2002) A two-dimensional quadrupole ion trap mass spectrometer. *Journal of the American Society for Mass Spectrometry* 13: 659–669. Copyright 2002, by the American Society for Mass Spectrometry.)

ion trap is shown in **Figure 4** where the front and rear sections are of length 12 mm and the center section is of length 37 mm. An rf potential at 1 MHz is applied to the linear ion trap, and an auxiliary ac potential is applied in dipolar mode across the rods in the  $x$ -direction of the center section. Ions are directed radially from the center section; in order to detect the ions externally, a 0.25 mm high slot was cut along the middle 30 mm of the center section of one rod as shown in **Figure 4**; a standard detector system is mounted in front of the slot.

**Modes of operation** In **Figure 2**,  $Q_0$  is an rf-only quadrupole in which the ion beam is focused collisionally to enhance the transmission of ions from  $Q_0$  to  $Q_1$ , an rf/dc quadrupole mass filter. Precursor ions are mass selected in  $Q_1$  and transmitted to  $Q_C$  where they are confined and subjected to resonant dissociation; the product ions are ejected axially and mass-selectively. In an MS/MS experiment, where

collision-induced dissociation (CID) is brought about by resonant excitation in  $Q_C$ ,  $Q_2$  serves merely to transmit the product ions at low pressure to the detector.

In an alternative arrangement, ions fall through a potential difference as they pass from  $Q_1$  to  $Q_C$  so that CID occurs in  $Q_C$ . The nascent product ions are accumulated in the linear ion trap  $Q_C$  and then ejected mass selectively to the detector.

In yet a further arrangement made possible by the serendipitous selection of the original experimental platform, ions fall through a potential difference as they pass from  $Q_1$  to  $Q_C$  so that, again, CID occurs in  $Q_C$ . The nascent product ions pass through  $Q_C$  and enter into and are accumulated within the linear ion trap  $Q_2$  that is operated at rf only. Ions confined in  $Q_2$  are excited radially and, in the fringing field at the exit of  $Q_2$ , are ejected axially and mass-selectively. In this mode, since  $Q_2$  is not pressurized directly, it is identified as a low-pressure linear ion trap.

**Ion trap capacities** A simple model for the comparison of ion trap capacities based on the volumes of the trapped ion clouds subjected to collisional focusing in each instrument yields

$$\begin{aligned} N_{2D,A} : N_{2D,B} : N_{3D} &= (\pi r_A^2 l_A) : (\pi r_B^2 l_B) : \frac{4\pi r_C^3}{3} \\ &= l_A : l_B : \frac{4r_C}{3} \end{aligned} \quad [3]$$

where  $N_{2D,A}$ ,  $N_{2D,B}$ , and  $N_{3D}$  are the ion capacities in the SCIEX, Thermo Finnigan, and quadrupole ion trap instruments, respectively;  $(\pi r_A^2 l_A)$ ,  $(\pi r_B^2 l_B)$ , and  $4\pi r_C^3/3$  are the occupied volumes of the same instruments, respectively. For collisionally focused ion clouds at a common rf potential and radial frequency,  $r_A = r_B = r_C = 1.0$  mm based on ion tomography experiments, the ratio  $N_{2D,A} : N_{2D,B} : N_{3D} = 95:22:1$ . This ratio suggests an ion capacity for the linear ion trap two orders of magnitude greater than that of the 3D ion trap.

### Characteristics of linear ion trap operation

**Trapping efficiency** The efficiency of trapping in  $Q_C$  approaches 100% for ions with 5–15 eV of kinetic energy over the pressure range  $1\text{--}17 \times 10^{-4}$  Torr. The high acceptance of ions into a linear trap is attributed to the absence of a quadrupole field along the  $z$ -axis.

**Mass discrimination** Ions injected along the  $z$ -axis into a linear ion trap as shown in **Figures 2** and **4** encounter minimal rf field in the  $z$ -direction. Thus, mass discrimination during ion injection and ion trajectory stabilization processes is much reduced in a linear ion trap; a wide mass range from 150 to 2000 Th can be trapped simultaneously with high efficiency.

**Ion isolation** Ion isolation has been demonstrated to be >95% efficient.

**Ion activation** Activation of ions isolated in a linear ion trap is carried out at  $q_x = 0.25$ , which is a compromise for efficient fragmentation (74%) and a relatively large fractional (72%) mass range for confinement of product ions.

**Tandem mass spectrometry**  $MS^n$  can be achieved by repeated cycles of isolation and activation.

**Spectral space charge limit** The onset of space charge perturbation corresponds to an ion density of  $\sim 460 \text{ ions mm}^{-3}$  that compares well with the value of  $\sim 400 \text{ ions mm}^{-3}$  for the 3D ion trap.

**Ion ejection** The efficiency of mass-selective radial ion ejection was 44% relative to the number of ions detected under mass-independent ion ejection conditions, yielding an overall efficiency of 12.7%. Mass-selective axial ejection yielded an overall extraction efficiency of 8% at  $5.0 \times 10^{-4}$  Torr to 18% at  $1.2 \times 10^{-3}$  Torr. The ejected ion signal intensity increased threefold as the auxiliary AC frequency was increased from 334 to 762 kHz.

**Enhanced mass resolution** Mass spectra with enhanced mass resolution are obtained with linear ion traps by reduction of the mass scanning rate and axial modulation amplitude. At a scanning rate of  $5 \text{ Th s}^{-1}$  and with an auxiliary frequency of 450 kHz applied to  $Q_C$  of **Figure 2**, a mass resolution ( $m/\Delta m$ ) of  $\sim 6000$  was observed for the protonated reserpine molecule.

**Sensitivity** A fivefold improvement in the detection limits of a LCQ Deca 3D ion trap has been demonstrated with the Thermo Finnigan linear ion trap. The observed extraction efficiency of 18% from  $Q_C$

indicates that the linear ion trap to be some 10 times more sensitive than a 3D device. The linear ion trap has the capability to become a highly sensitive scanning mass spectrometer.

**Low-pressure linear ion trap,  $Q_2$**  The operating pressure of the  $Q_2$  linear ion trap is <1% of that of the  $Q_C$  linear ion trap, yet the trapping efficiency for the low-pressure  $Q_2$  linear ion trap is  $\sim 45\%$  for ions with kinetic energies in the range 5–15 eV.

**Comparison of performance** The product ion mass spectrum of protonated reserpine can be used to affect a comparison of the performances of a TSQ, a  $Q_C$  linear ion trap, and a low-pressure  $Q_2$  linear ion trap. The TSQ mass spectrum shows fragment ions to  $m/z$  174; the base peak of  $m/z$  195 was observed at a signal intensity of  $1375 \text{ counts s}^{-1}$ . The  $Q_C$  linear ion trap mass spectrum shows the middle range ( $m/z$  350–450) fragment ions having higher relative signal intensities; the base peak of  $m/z$  195 was observed at a signal intensity of  $15\,700 \text{ counts s}^{-1}$ ; that is, some 11 times more intense. The low-pressure  $Q_2$  linear ion trap mass spectrum is shown in **Figure 5**; the relative fragment ion intensities are similar to those obtained with the  $Q_C$  linear ion trap and the base peak,  $m/z$  195, was observed at a signal intensity of  $7000 \text{ counts s}^{-1}$ ; that is, some five times more intense than the TSQ. The  $Q_2$  linear ion trap showed the highest mass resolution and signal-to-noise ratio.

### Cylindrical Ion Trap Mass Spectrometer

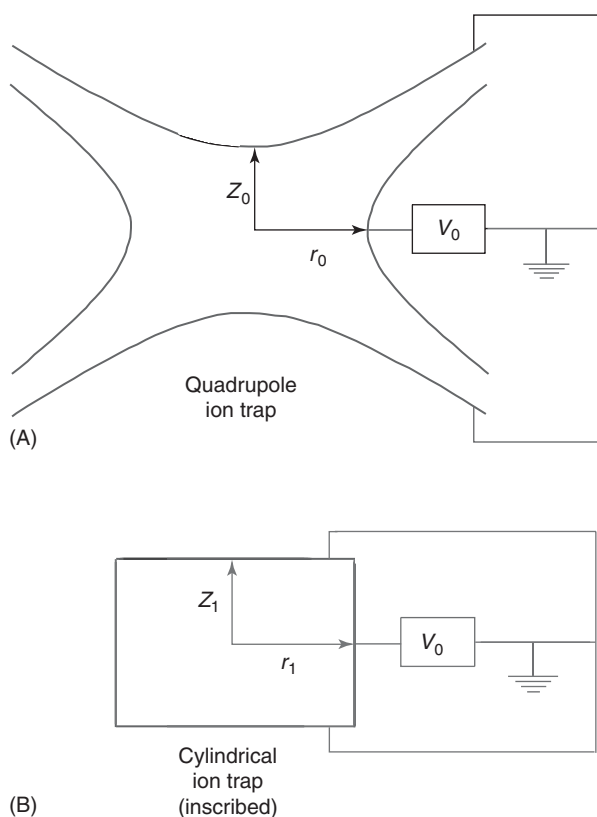

A cylindrical ion trap, CIT, configured as the inscribed cylinder to a 3D quadrupole ion trap is shown in **Figure 6**. A CIT can be fabricated readily from a polished metal cylinder with an internal radius of a few millimeters and two disks perforated for admission of electrons or ions and for ejection of ions.

The cylindrical device is easier to construct than a 3D ion trap having hyperbolic electrodes, and variation of the ratio  $r_c:2z_c$  (radius of cylinder to height of CIT) is facile. Research into CITs has focused upon small CITs, described as mini-CITs, for application as tandem mass spectrometers and for the development of arrays of mini-CITs. In order to achieve in a mini-CIT a given value of  $q_z (= -q_x \text{ from eqn [2]})$ , an elevated drive frequency is required to compensate for the reduced value of  $r_c$ . In this manner, a potential well of sufficient magnitude is facilitated that permits excitation of ions confined within the mini-CIT.

**Miniature cylindrical ion traps (mini-CITs)** A mini-CIT is defined according to the radius,  $r_c$ , of the ring or barrel electrode; when  $r_c$  is <5 mm, the CIT is classed as miniature. Mass analysis using the

**Figure 5** Product ion mass spectrum of protonated reserpine,  $m/z$  609, obtained with the  $Q_2$  linear ion trap at a mass scan rate of  $5200 \text{ Th s}^{-1}$ . **Figure 6** Comparison of geometries and operating modes for the three-dimensional quadrupole ion trap (QUISTOR) and a cylindrical ion trap. (A) QUISTOR,  $r_0^2 = 2z_0^2$ ; (B) 'inscribed' cylindrical ion trap,  $r_1^2 = 2z_1^2$ . (Reproduced with permission from March RE, Hughes RJ, and Todd JFJ (1989) *Quadrupole Storage Mass Spectrometry*. Chemical Analysis Series, vol. 102. New York: Wiley. © 1989 Wiley & Sons.)

mass-selective axial instability scan in a CIT mass spectrometer has been demonstrated as has  $MS^n$ . The driving force for the development of CITs as field-portable instruments is the need for *in situ* analysis of toxic pollutants and detection of chemical warfare (CW) agents. A field-portable CIT must have high sensitivity and specificity, good precision and accuracy, high speed of analysis, be capable of continuous operation *in situ* for extended periods, and be of low weight, compact, and battery powered.

**Miniaturization** Cooks and co-workers have described the construction and performance of a mini-CIT mass spectrometer that has a mass/charge ratio range of  $\sim 250 \text{ Th}$  and tandem mass spectrometric capability. The cylindrical barrel is of internal radius,  $r_c = 2.5 \text{ mm}$  and the separation ( $2z_c$ ) of the end-cap electrode disks is  $5.77 \text{ mm}$ . A schematic representation of the ion source, ion optics, mini-CIT, and detector is shown in Figure 7. The end-cap electrode spacing was adjusted to  $5.77 \text{ mm}$  to add a small octapolar field to compensate for field defects due to perforations in the end-cap electrodes.

These electrode dimensions provided a mass/charge ratio range of  $\sim 250 \text{ Th}$  at maximum drive RF voltage amplitude of  $800V_{0-p}$  oscillating at  $2 \text{ MHz}$ . For a typical tandem mass spectrometer experiment, these experimental parameters correspond to irradiation of  $m/z$  250 at, say,  $q_z = 0.4$  ( $352V_{0-p}$ ) to yield a product ion mass spectrum from  $m/z$  110 to  $m/z$  250. The trapping well depth,  $D_z$ , for  $m/z$  250

at  $q_z = 0.4$  is given as

$$D_z \approx \frac{V_{0-p} q_z}{8} \quad [4]$$

such that  $D_z \approx 352 V_{0-p} \times 0.4/8 = 17.6 \text{ eV}$ , that is, more than sufficient for CID.

**Portable miniature CIT** The mini-CIT mass analyzer accounts for <1% of the total volume and weight of the instrument; thus, the major miniaturization effort

**Figure 7** A schematic representation of the ion source, ion optics, CIT, and detector. The filament, mounting hardware, and gate electrode are based on those used in the Finnigan ITS-40-instrument. (Reproduced with permission from Patterson GE, Guymon AJ, Riter LS, *et al.* (2002) Miniature cylindrical ion trap mass spectrometer. *Analytical Chemistry* 74: 6145–6153. Copyright (2002) American Chemical Society.)

was directed to the ancillary components. The weight of version 5 mini-CIT was 35 kg including the computer (plus 20 kg for the system battery), and measured  $\sim 45 \times 60 \times 71 \text{ cm}$ ; a smaller version 7 instrument of 16 kg and measuring  $28 \times 70 \times 18 \text{ cm}$  has also been constructed. In a mini-CIT, the oscillation amplitude of an ion at a given secular frequency is smaller than in an ion trap of standard size; hence, ions experience fewer ion/neutral collisions per rf cycle and these collisions are of diminished collision energy. Therefore, a mini-CIT can be operated at a higher-than-normal pressure and the pumping requirements are reduced.

**Ionization source** Electron impact (EI) ionization is employed using a standard EI filament assembly from a Finnigan ITS-40 ion trap instrument. The entire circuit, including power unit and test points, is enclosed in a  $5 \times 5 \times 1 \text{ cm}$  volume. The electron flow into the CIT is gated during ion cooling and mass analysis.

**Waveforms** Operation of a mini-CIT requires five waveforms: drive rf (2.000 MHz) and rf amplitude modulation potentials, ion isolation waveform, and ac potentials for ion excitation and for mass-selective axial ejection. Typical ac amplitude used in the mini-CIT for CID is  $\sim 2V_{0-p}$  and is applied in dipolar mode to the end-cap electrodes. The frequency used for resonant ejection is an octapole resonance that causes rapid ejection of ions. In **Figure 8** is shown a typical timing diagram of scan function by which an EI mass spectrum may be obtained. A scan function is a diagram showing the temporal relationships of the various potentials applied during

**Figure 8** Timing diagram or scan function for a miniature CIT. (Reproduced with permission from Patterson GE, Guymon AJ, Riter LS, *et al.* (2002) Miniature cylindrical ion trap mass spectrometer. *Analytical Chemistry* 74: 6145–6153. Copyright 2002, by American Chemical Society.)

**Figure 9** Mass spectra obtained from PFTBA with two miniature CITs. (A) A lower mass range obtained with version 5 miniature CIT. (B) A higher range mass spectrum, also of PFTBA, obtained with version 7 miniature CIT. (Reproduced with permission from Patterson GE, Guymon AJ, Riter LS, *et al.* (2002) Miniature cylindrical ion trap mass spectrometer. *Analytical Chemistry* 74: 6145–6153. the course of an ion trap experiment. The duration of application of each of the potentials and of each cooling period is indicated. The isolation waveform is indicated schematically as a square wave with an interposed slot corresponding to the ion secular frequency of the isolated species. The CID waveform is a single frequency sine wave. The analysis waveform is a fixed frequency sine wave increasing in amplitude at a constant rate.

### System performance

**Mass calibration** In Figure 9 are shown two mass spectra obtained with mini-CITs using perfluorotri-*n*-butylamine (PFTBA), a commonly used mass calibrant. The low range mass spectrum in Figure 9A was obtained with version 5 mini-CIT using a scan function similar to that shown in Figure 8. A mass range from 48 to 250 Th was scanned in 15 ms, giving a ramp rate of  $\sim 13\,500\text{ Th s}^{-1}$ . The expected base peak is  $m/z$  69 ( $\text{CF}_3^+$ ). The higher range mass spectrum of PFTBA in Figure 9B was obtained using the smaller version 7 mini-CIT. The mass calibrations were linear with  $R^2 = 0.9999$ .

**Tandem mass spectrometry** In Table 1 are shown mass spectra from some mini-CIT experiments together with mass spectra obtained by MS/MS and MS/MS/MS. The intensity of each ion species is given in parentheses in units of volts to illustrate the absolute performance of the instrument.

The major peaks observed from *p*-nitrotoluene are shown in the MS column; the base peak is  $m/z$  137 of intensity 4.8 V. The MS/MS isolation column gives the peak heights of ions after isolation but prior to CID. For *p*-nitrotoluene, the  $m/z$  137 ion has an

<sup>c</sup>Helium was used as the bath/buffer/collision gas.

intensity of 4.6 V following isolation; thus the isolation procedure has an efficiency of 96%. The signal intensity (0.4 V) of  $m/z$  121 constitutes a percentage residual ion abundance of 8%.

In the MS/MS dissociation column are presented the components of the product ion mass spectrum of  $m/z$  137; CID of  $m/z$  137 yields a residual ion signal intensity of 2.0 V for  $m/z$  137, and intensities of 2.0, 0.2, and 0.3 V for  $m/z$  121, 107, and 91, respectively. Thus, the attenuation of the molecular ion of  $m/z$  137 is 56% (i.e., a dissociation efficiency of 44%). The total ion intensity of the components of the product ion mass spectrum is 4.5 V that, when compared with the total ion intensity after the isolation stage, 5 V, yields an overall ion retention efficiency during CID of 90%.

The fifth and sixth columns show data from MS/MS experiments that permit evaluation of the isolation and CID efficiencies and retention of total

ion charge; acetophenone provides an almost ideal example. From the fourth and fifth columns, the isolation efficiency for  $m/z$  105 is shown to be 86% and, from the fifth and sixth columns, the dissociation efficiency is 33% while the ion retention efficiency is 77%. The MS<sup>3</sup> product ion mass spectrum shows unchanged  $m/z$  105 and a fragment ion of  $m/z$  77. The overall efficiency of the formation of  $m/z$  77, through two repeated processes of isolation and CID, from  $m/z$  120 is 5%. With complete dissociation of  $m/z$  120 and  $m/z$  105, the overall efficiency could be increased to 19%; this MS<sup>3</sup> achievement is remarkable for a mini-CIT.

**Limit of detection** The limit of detection for the CW simulant, methyl salicylate, was estimated as 1 pg.

**Miniature cylindrical ion trap array** An approach to the rapid screening of large numbers of samples in the areas of proteomics, industrial process monitoring, and metabolomics is to use a multiplexed inlet system with a multiplexed mass spectrometer having an equal number of parallel sample channels. To this end, a high-throughput mini-CIT array mass spectrometer has been developed and tested.

The array consists of four mini-CITs arranged like the rods of a mass filter shown in **Figure 1**. Each mini-CIT has a barrel electrode with  $r_c = 1.25$  mm, its own inlet system, filament assembly, and detector, all within a common vacuum manifold and with a single set of control electronics. Sample ions are generated externally to the mini-CIT and transported through an Einzel lens into each mini-CIT, as shown

**Figure 10** A schematic representation of two of the four parallel analysis channels in the  $2 \times 2$  array of mini-CITs. (Reproduced with permission from Tabert AM, Griep-Raming J, Guymon AJ, and Cooks RG (2003) High-throughput miniature cylindrical ion trap array mass spectrometer. *Analytical Chemistry* 75: 5656–5664. Copyright 2003, by American Chemical Society.)

**Figure 11** Mass spectra obtained from a high-throughput experiment during which three channels of the four-channel array instrument were used to analyze three different compounds simultaneously: 1, acetophenone; 2, bromobenzene; 3, 1,3-dichlorobenzene; 4, idle. (Reproduced with permission from Tabert AM, Griep-Raming J, Guymon AJ, and Cooks RG (2003). High-throughput miniature cylindrical ion trap array mass spectrometer. *Analytical Chemistry* 75: 5656. in Figure 10 for two of the four parallel channels. The mass/charge ratio range is  $m/z$  50–500 and a mass resolution ( $m/\Delta m$ ) of 1000 is obtained at  $m/z$  300. Because each channel has its own inlet system, four compounds can be examined in the array. In Figure 11 are displayed the results of a high-throughput experiment in which three of the four channels were operated simultaneously; acetophenone, bromobenzene, and 1,3-dichlorobenzene were introduced into channels 1, 2, and 3, respectively. Channel 4 was idle. The successful operation of this array of mini-CITs is a remarkable achievement.

## Introduction

The measurement of the time-of-flight (TOF) of ions of near constant energy has been used to determine ion mass-to-charge ratios ( $m/z$ ) since the 1940s. However, it was not until 50 years later that TOF quickly became a mainstream device in mass spectrometry (MS). The reasons for the renaissance of this technique include: the development of supporting technologies of high-speed timing electronics (especially high-speed signal digitizers); high-speed data processing capability of computers; development of focal plane electron multipliers that deliver pulses with nanosecond rise-times; the invention of the ion mirror; development of matrix-assisted laser desorption ionization (MALDI) sources; and the development orthogonal acceleration instrument geometries for gating ions from a range of continuous ion sources that are widely used. Prior to these developments, TOF-MS was not able to provide selectivity (mass resolution) or sensitivity that was competitive with scanning mass spectrometers based on quadrupole and magnetic sector technologies.

During the 1990s, the increasing utility of MALDI and electrospray ionization (ESI) sources to deliver

intact gas-phase ions of polar, thermally labile, and high molecular weight biomolecules provided impetus to develop TOF-MS. This was because of the intrinsic ability of TOF-MS to transmit and detect ions of high  $m/z$  and its emerging high sensitivity and speed. The potential of TOF for bioanalysis was foreshadowed by the  $^{252}\text{Cf}$  Plasma Desorption mass spectrometers in the 1970s; however, the greater utility of MALDI and ESI and the existence of practical approaches to combine these sources with TOF have led to a proliferation of TOF-MS.

The majority of applications of TOF-MS are currently in the area of bioanalytical chemistry and particularly the analysis of whole proteins, their peptide fragments, and nucleic acids. The importance of protein analysis is a consequence of the explosion of data from mapping of the human genome and genomes of several other species. The genes express proteins and the function of specific proteins (hence that of their genes) is now a critical concern in many areas of medicine, drug discovery, and biochemistry. TOF-MS together with advancing separation techniques has become an enabling technology in the life sciences because of its remarkable ability to characterize these molecules even when they are present in very low abundance in complex mixtures.

The growing demands from life science research is a major force driving the development TOF-MS technology. The maturation of the technology has allowed TOF-MS to be adopted as a mainstream mass spectrometer with the special advantages of high speed as well as high resolution and mass

in Figure 10 for two of the four parallel channels. The mass/charge ratio range is  $m/z$  50–500 and a mass resolution ( $m/\Delta m$ ) of 1000 is obtained at  $m/z$  300. Because each channel has its own inlet system, four compounds can be examined in the array. In Figure 11 are displayed the results of a high-throughput experiment in which three of the four channels were operated simultaneously; acetophenone, bromobenzene, and 1,3-dichlorobenzene were introduced into channels 1, 2, and 3, respectively. Channel 4 was idle. The successful operation of this array of mini-CITs is a remarkable achievement.

## Introduction

The measurement of the time-of-flight (TOF) of ions of near constant energy has been used to determine ion mass-to-charge ratios ( $m/z$ ) since the 1940s. However, it was not until 50 years later that TOF quickly became a mainstream device in mass spectrometry (MS). The reasons for the renaissance of this technique include: the development of supporting technologies of high-speed timing electronics (especially high-speed signal digitizers); high-speed data processing capability of computers; development of focal plane electron multipliers that deliver pulses with nanosecond rise-times; the invention of the ion mirror; development of matrix-assisted laser desorption ionization (MALDI) sources; and the development orthogonal acceleration instrument geometries for gating ions from a range of continuous ion sources that are widely used. Prior to these developments, TOF-MS was not able to provide selectivity (mass resolution) or sensitivity that was competitive with scanning mass spectrometers based on quadrupole and magnetic sector technologies.

During the 1990s, the increasing utility of MALDI and electrospray ionization (ESI) sources to deliver

intact gas-phase ions of polar, thermally labile, and high molecular weight biomolecules provided impetus to develop TOF-MS. This was because of the intrinsic ability of TOF-MS to transmit and detect ions of high  $m/z$  and its emerging high sensitivity and speed. The potential of TOF for bioanalysis was foreshadowed by the  $^{252}\text{Cf}$  Plasma Desorption mass spectrometers in the 1970s; however, the greater utility of MALDI and ESI and the existence of practical approaches to combine these sources with TOF have led to a proliferation of TOF-MS.

The majority of applications of TOF-MS are currently in the area of bioanalytical chemistry and particularly the analysis of whole proteins, their peptide fragments, and nucleic acids. The importance of protein analysis is a consequence of the explosion of data from mapping of the human genome and genomes of several other species. The genes express proteins and the function of specific proteins (hence that of their genes) is now a critical concern in many areas of medicine, drug discovery, and biochemistry. TOF-MS together with advancing separation techniques has become an enabling technology in the life sciences because of its remarkable ability to characterize these molecules even when they are present in very low abundance in complex mixtures.

The growing demands from life science research is a major force driving the development TOF-MS technology. The maturation of the technology has allowed TOF-MS to be adopted as a mainstream mass spectrometer with the special advantages of high speed as well as high resolution and mass

accuracy. Consequently, it is experiencing increasing use in areas such as environmental sciences and is enabling new areas such as high-speed gas chromatography/mass spectrometry (GC-MS) and comprehensive GC-MS (GC  $\times$  GC-MS). The ability of benchtop GC-TOF instruments to work with field ionization sources and provide accurate molecular weight information for many compounds that do not give molecular ions under standard conditions of electron ionization is also noteworthy.

This article will present the basic theory of TOF-MS and will consider the most important instrument configurations and applications. The utility of TOF-MS compared to other mass analyzers will be discussed.

## Theory of Operation

In the simplest TOF-MS system an ideal population of ions of different masses is located in a plane at a fixed distance from a detector and accelerated from rest toward the detector. Acceleration is caused by the application of typically one or two electric fields set up between grids in the accelerator as shown in **Figure 1**. Ions of mass  $m$  and charge  $q$  (where  $q$  is accounted for by an integer number of electron charges  $ze$ ) are either generated in bunches or accelerated as a bunch by pulsing the first field. The two fields –  $E_1$  and  $E_2$  – are aligned in the TOF direction. Initiation of acceleration is a start event and this triggers a timing device. An ion will travel a distance of  $s_1$  then  $s_2$  in the fields gaining kinetic energy  $q(E_1s_1 + E_2s_2)$ . The length of the combined acceleration regions is typically a few centimeters. This is related to velocity,  $u_{\text{TOF}}$ , in the TOF direction by  $0.5u_{\text{TOF}}^2$  (eqn [1]). A drift region of length  $D$  follows and the time for ions to traverse it is given by  $t_D$  in eqn [3]. Drift regions vary in length from about 0.5 m to 3 m. Since the velocity is inversely proportional to the square root of  $m/z$  (eqn [2]), the ions will separate as lighter ions traverse the drift region faster than heavier ions (eqn [3]). A planar detector is normally

used to convert the ion arrival event into an electrical signal whose time relative to the start event is recorded digitally. The ion arrival events distribute along a  $(m/z)^{0.5}$  axis that is reliably calibrated:

$$0.5mu^2 = ze(E_1s_1 + E_2s_2) \quad [1]$$

$$u_{\text{TOF}} = \sqrt{\frac{2ze(E_1s_1 + E_2s_2)}{m}} \quad [2]$$

$$t_D = \frac{D}{e^{0.5}(E_1s_1 + E_2s_2)^{0.5}} \times (m/z)^{0.5} \quad [3]$$

The total ion drift energy in TOF-MS is typically 2–30 keV and this gives a flight time for the heaviest ion in the order of 50–100  $\mu\text{s}$ . Thus, the repetition rate of the TOF-MS is  $\sim 10$ –20 kHz and one repetition is often referred to as a ‘shot’. Ions differing in mass by 1 Da are typically separated in arrival time by several nanoseconds and thus a digitizer with a sampling rate of at least  $2 \times 10^8 \text{ s}^{-1}$  is required.

Ions’ arrival times for a group of ions of the same  $m/z$  distribute to form a peak centered at a time  $t$  easily computed from the laws of motion. A distribution of ion arrival time with a full-width at half-maximum height (FWHM) of  $\Delta t$  results from nonideal starting parameters: the ions do not all start at the same distance from the detector; the ions do not all start from rest but are typically subject to a Boltzmann distribution of molecular speed in all directions; and the ions do not all form at the same time and/or the registration of their start events is subject to error. These three factors are, respectively, referred to as the initial spatial, velocity, and temporal dispersions. In addition, the arrival of the ion at the detector is registered as a pulse with a more-or-less constant rise-time and fall-time making a further contribution to temporal spread. The effect of  $\Delta t$  is to place a limit on the difference in  $m/z$  that can be discerned by TOF-MS. Resolution in MS is expressed as  $m/\Delta m$  where for singly charged ions,  $\Delta m$  is the FWHM mass width of a peak at mass  $m$ . Differentiating eqn [3] with respect to  $m$  allows resolution to be expressed conveniently in terms of time:

$$m/\Delta m = t/2\Delta t \quad [4]$$

The temporal dispersion is typically a constant contributor to  $\Delta t$  (i.e., independent of  $m/z$ ); however, the contribution of spatial and velocity dispersions to  $\Delta t$  scales with  $m/z$ . The initial dispersions are typically uncorrelated so their effects add in quadrature. It is usual that the temporal dispersion is small compared to the others except at very low  $m/z$  and therefore it has an insignificant effect on resolution at higher masses. Therefore, the resolution of a TOF mass

**Figure 1** Schematic diagram of a linear TOF-MS showing light (green) and heavy (red) ions in the accelerator and later in the drift region. Two accelerator fields are shown.

spectrometer is nearly constant over most of its mass range and is significantly lower than this value only at very low mass.

It is possible to correct for initial dispersions in isolation. When two or more dispersions are significant and not correlated there is no generally practical way to compensate for their effects. Mass resolution is therefore limited. However, some fundamental focusing methods to address individual dispersions together with novel ion-optical configurations provide mass resolution in the range 5000–20 000 in commercial TOF-MS systems.

### Spatial Focusing

This method to correct for a spread of initial ion position was first described by Wiley and McLaren in the 1950s. The acceleration fields are arranged so that ions (of the same  $m/z$ ) that are further from the detector are accelerated through a longer distance ( $s_1$ ) and reach a higher velocity than their counterparts that are initially closer to the detector. The faster ions catch up with the slower ions at the detector and arrive simultaneously. The residual arrival-time spread from spatial spread can be kept insignificant for typical spatial dispersions of  $\sim 2$  mm.

### Time-Lag Focusing

The initial velocity spread is converted to a spatial spread by allowing a delay between ionization and acceleration. Ions separate to create a correlation between position and velocity. Spatial focusing can be applied to correct this. This method was also developed by Wiley and McLaren and the conditions (length of delay) must be adjusted for each  $m/z$ . Time-lag focusing does not work well when a significant spatial and velocity spread are present simultaneously. As will be discussed later, time-lag focusing has recently been adapted to greatly increase the resolution in MALDI TOF-MS.

### Energy and Spatial Focusing Devices

In a TOF-MS configuration named the ‘mass reflectron’, Mamyryn and Shmikk found a way to increase resolution by employing an electrostatic ion mirror in the drift region. The effect of initial velocity and spatial dispersions is minimized by applying a strong single acceleration field and this creates a spatial focus at  $2s_1$  in the drift region. Ions of the same mass pass through this point in a spatially and temporally tight bunch but with a large energy spread. The more energetic (faster) ions penetrate more deeply into the ion mirror before they turn around. The time to travel through the mirror is inversely proportional to

**Figure 2** Schematic diagram of a reflecting TOF-MS showing light (green) and heavy (red) ions in the accelerator and later in the drift region. Accelerator, deflection, and mirror fields are shown.

the square root of the ion's drift energy. The slower ions are allowed to catch up with faster ones that have further to travel. The arrangement is configured so the point at which the ions catch up is at the detector. The configuration of the ion mirror is shown in Figure 2. Another advantage of the ion mirror is that the drift region is effectively used twice and this reduces instrument size. A long total drift length is important because it increases  $t$  while the correction devices keep  $\Delta t$  small. Resolution is substantially increased by increasing the drift distance. One recent instrument is configured with a second mirror at the opposite end of the drift region relative to the main mirror. Ions therefore are made to traverse the drift region four times before detection. This device is called a ‘W’ mirror because it creates a trajectory shaped like the letter ‘W’. It significantly increases resolution (a factor of  $\sim 2$ ) but the cost is that a significant loss of ion transmission occurs because ions make more passes through grids (typical grid transmission 50–90%).

Another device that provides isochronous focusing with respect to energy in TOF-MS is the electric sector as introduced by Poschenrieder. As with the mirror, the more energetic ions travel a longer trajectory and therefore take longer to travel through the sector. Slower ions are once again allowed to catch up at the detector. Electric sectors usually require slits that substantially reduce ion transmission. Ion mirrors have generally higher transmission than the electric sector and together with the convenience of doubling the drift distance without increasing the size of the instrument they are the preferred energy correcting device in most TOF-MS systems.

## Orthogonal Acceleration

A continuous or pseudocontinuous ion beam is arranged orthogonally to a TOF mass spectrometer. Orthogonal acceleration (oa) was developed independently by Guilhaud and Dodonov in the 1980s and it is an excellent way to couple continuous ion sources to a TOF mass analyzer. In oa-TOF-MS, a nearly parallel ion beam has ideally no velocity spread in the direction orthogonal to it (Figure 3). This direction is chosen for the TOF mass analysis and the finite spatial spread is corrected with a linear or reflecting instrument geometry. The arrangement has several important advantages:

- The small zero-centered velocity spread in the TOF direction allows excellent resolution and mass accuracy after the spatial spread is corrected.
- A substantial length of the continuous ion beam may be sampled and the energies of the ion beam and the orthogonally accelerated ion packets can be arranged so that the flight time in the mass analyzer is about the same as the time for a new section of beam to enter the accelerator. This results in an increase in the duty cycle, i.e., a substantial increase in sensitivity compared to scanning mass spectrometers because much greater proportion of ions produced can be detected.
- Most continuous ion sources are suited to oa-TOF-MS; it can also be used effectively as the final mass analyzer in hybrid instruments which combine two mass spectrometers in an approach called tandem mass spectrometry or MS/MS.

**Figure 3** Arrangement of an oa-TOF-MS. A continuous ion beam enters from the source (top left) and sections of this beam are periodically accelerated from the orthogonal accelerator (oa) in a direction orthogonal to the beam. The packet of ions so formed is analyzed by the reflecting TOF-MS while (simultaneously) a new beam is forming in the oa.

## Ion Detection

Either a discrete dynode electron multiplier or, more commonly a microchannel plate converts the arrival of an ion into a cascade of secondary electrons. A gain of  $10^5$ – $10^7$  in charge occurs in these detectors. The pulse that results from this charge is detected by a digitizer. Digitizers generally fall into two categories. Time-to-digital converters (TDC) simply record the time of a stop event in a list. The spectrum is generated after several shots have been acquired and a histogram of stop events is constructed. This approach has the advantages that null data are not processed and the rise-time of the stop pulses from the detector is sensed over a threshold giving a very small temporal contribution to the peak width. The TDC has the disadvantage of coincidence losses. If two or more ions arrive within the same time-bin they are seen as one. This limits the dynamic range for high count rates. Transient recorders are an alternative type of digitizer. Here, a fast analog-to-digital converter converts the output of the detector into a time transient. Null data are recorded and must be summed into the final spectrum usually over a few tens of shots. Transient recorders typically operate at sampling rates of  $0.5$ – $4 \times 10^9 \text{ s}^{-1}$  and at these rates the digital amplitude resolution is limited to 8 bits. Summing data from subsequent shots into 16 bit memory increases the dynamic range to  $\sim 10^3$ – $10^4$ . The limitation comes at the low count rates due to digital noise.

## TOF-MS Instrument Configurations and Applications

Applications of MS tend to be based on a few main types of ion sources. The most important of these will be discussed in detail in this article.

### MALDI TOF-MS

In MALDI, a pulsed laser is fired at a solid sample mixed with a large molar excess of a matrix (e.g., 1000:1). Typically, MALDI instruments use a 337 nm pulsed ultraviolet laser and the matrix is a substituted aromatic acid (e.g., 2,5-dihydroxybenzoic acid). A small amount of matrix in an irradiated area of  $\sim 100 \mu\text{m}$  (diameter) efficiently absorbs the laser energy and vaporizes. Sample molecules, typically biopolymers or peptides, are desorbed and ionized in this process (Figure 4). MALDI TOF-MS is an important application accounting for much of TOF's recent revival. The first generation of MALDI instruments suffered from low resolution that further degraded with mass. This was largely due to the energy spreads imparted to desorbing ions in

**Figure 4** Peptide mass fingerprints of recombinant proteins (EPR) used in doping: MALDI TOF-MS spectrum of (A) Glu-C digested EPR and (B) Glu-C digested and deglycosylated EPR. (Reprinted with permission from Stanley and Poljak (2003) *Journal of Chromatography B* 785: 205–218; © Elsevier.)

collisions with the desorbing matrix. Since ions are generated from a surface at a well-defined time (laser pulse) it is possible to correct for the initial spread of energy by delaying the acceleration. The velocity spread prior to acceleration leads to a correlated spatial spread that may be corrected as already discussed. The correction is mass dependent so that optimal resolution is available over a limited mass range. Care must also be used in calibration as the mean desorption velocity depends on experimental conditions (e.g., matrix and laser power) in such a way that the mass calibration relationship is less predictable than TOF-MS with ions starting with zero average velocity. Despite these minor shortcomings, delayed extraction (DE) has greatly improved the selectivity and sensitivity of MALDI and has contributed to the establishment of MALDI as an essential tool in bioanalytical chemistry.

It is often useful to observe the fragmentation patterns of ions in MS. This can give insights into their structure. Ions that fragment in the drift region prior to the ion mirror are called metastable ions. The fragment ion carries a proportion of the original ion energy relative to its fraction of the mass of the precursor. The fragment therefore has a shorter flight-time through the mirror than the precursor and it appears at a lower apparent mass. Conditions in

DE-MALDI TOF-MS systems can be set up to detect these ions and determine their  $m/z$  for structure determination. The technique is called postsource decay and it is particularly important in determining the sequence of amino acids in peptides formed from proteolytic digestion of proteins.

MALDI has recently been shown to be highly suited to orthogonal acceleration TOF-MS. The energy spread of desorbed ions is collapsed by a process of collisional cooling. Ions undergo several nondestructive collisions with a cool collision gas in an ion guide device. The ion guide is typically a radiofrequency-only quadrupole or hexapole. The ions cool to the temperature of the collision gas and achieve a correspondingly narrow energy spread. After collisional cooling the ions are reaccelerated with a dc electric field and formed into a pseudocontinuous ion beam that is the source for an oa-TOF-MS. As well as eliminating the problems associated with energy spreads in the MALDI process, this geometry also provides ions with zero average velocity in the TOF direction and this helps make the calibration of the mass scale more accurate. Resolution of 5000–15 000 can be achieved with these instruments. Another advantage of MALDI oa-TOF-MS is that MS/MS can be done readily with this instrument configuration as discussed under Tandem TOF-MS instruments later in this article.

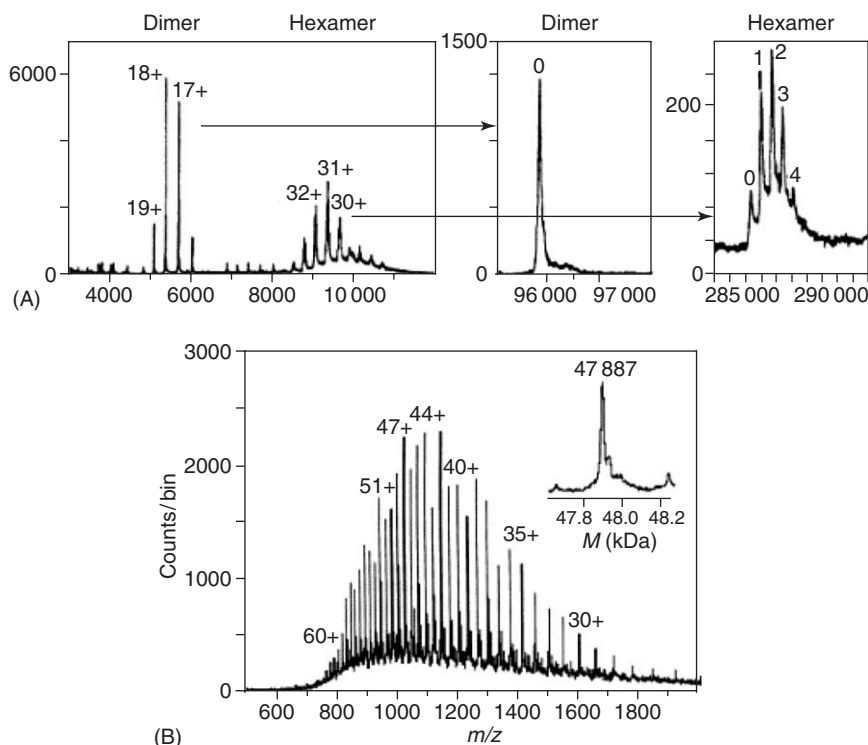

### Electrospray TOF-MS

ESI sources have become widespread in MS because they produce abundant molecular ions for polar and thermally labile molecules over a very wide mass range and the atmospheric pressure ionization technique is ideally suited to coupling with liquid chromatography. Molecules are typically ionized in acidic solution and sprayed from a needle to which high voltage is applied. Tiny droplets of ion containing liquid evaporate and leave intact ions of involatile molecules in the gas phase. These are sampled into the mass spectrometer through an orifice. Multiple charging occurs for larger species. For example, peptides up to a mass of 2 kDa typically form in charge states from +1 to +3. Large intact proteins and nucleic acids with masses  $10^4$ – $10^5$  Da can display charge states in the  $+10^1$  to  $+10^2$  charges. Negative ions may also be selected by reversing ion source potentials and using basic buffers. Initially, ESI was used with quadrupole mass analyzers. Though having a limited mass range compared to the masses of the molecules typically analyzed by ESI, the multiple charging of molecular ions almost always brought  $m/z$  into the range of the quadrupole. In

1991, Dodonov's group demonstrated the orthogonal acceleration instrument geometry with an ESI source. It soon became apparent that the higher sensitivity and the superior resolution of oa-TOF-MS was a compelling reason to develop these instruments commercially. Moreover, within 5 years, extremely useful hybrid tandem quadrupole oa-TOF systems established a new benchmark in sensitivity and selectivity for bioanalytical MS. In addition to these advantages, the ESI TOF-MS configuration has shown that ESI ions of proteins can be generated to retain their structure and noncovalent complexes are observed in relatively low charge states. This gives rise to  $m/z$  well outside the range of quadrupole mass analyzers. For example, the ESI TOF-MS spectrum in Figure 5 reveals the interaction between citrate synthase hexamer and an enzyme inhibitor. The hexamer ions are observed at  $m/z \sim 7000$ .

### MS/MS on Electrospray and MALDI Hybrid Quadrupole TOF-MS Instruments

Tandem mass spectrometry (MS/MS) is now widely used in analytical science as a way to increase specificity and sensitivity in chemical analysis. The

**Figure 5** (A) Electrospray mass spectra of (9 mmol L<sup>-1</sup> subunit concentration) recombinant *Escherichia coli* citrate synthase in a bicarbonate buffer at pH 7.5 with 4.5 mmol L<sup>-1</sup> nicotinamide adenine dinucleotide (NADH) inhibitor. Dimer and hexamer complexes are evident as are the addition of NADH adducts (1–4) to the hexamer. (Reprinted with permission from Ayed *et al.* (1998) *Rapid Communications in Mass Spectrometry* 12: 339–344; © John Wiley & Sons Ltd.) (B) In contrast to A, the spectrum obtained under denaturing conditions (water/methanol 1/1 v/v + 5% acetic acid, pH ~2.5) in which only the monomer in high charge states is observed. (Additional data for B provided by the authors referred to in A.)

use of two or more mass analyzers in series, with a collision cell to promote ion fragmentations between them, allows additional 'purification' by selecting specific precursor molecular ions from a mixture for further analysis and characterization. This is often required when complex mixtures of tryptic peptides are separated by LC and two or more species co-elute. The most widely used MS/MS method in biomolecular analysis is to obtain the product ion spectrum of a precursor molecular ion. For example, **Figure 6** shows the product ions formed when the doubly charged molecular ion of a neuroendocrine peptide is fragmented to reveal the characteristic collisional fragmentation of the amide bonds along the peptide backbone, producing 'b' and 'y' series ions corresponding to charge retention on the N and C terminus, respectively. The resolution and signal-to-noise ratio are impressive in these results from the first reported hybrid quadrupole TOF-MS system shown in **Figure 7**. MS(1) is static and the quadrupole transmits ~100% of the ions to the TOF-MS(2). The efficient duty cycle of the TOF-MS(2)

together with its high resolution combine to make this configuration preferable to MS/MS systems based on a scanning MS(2).

Product scans of this type are very important in protein characterization because the difference in mass of the y and b series ion can reveal the amino acid sequence for a domain of the peptide. This process called *de novo* sequencing involves searching for the domain in protein databases and usually a sequence of a few amino acids can lead to successful identification of the original native protein. A particularly powerful feature of hybrid quadrupole TOF-MS systems is their ability to perform information dependent analysis (IDA). During the elution of an LC peak, software automatically identifies the molecular ions and sets up to collect MS/MS product spectra of (typically) doubly charged molecular ions above a preset abundance. TOF-MS is fast and sensitive enough in this application to cope with several (e.g., up to five) peptides co-eluting. More are possible but the quality of the data starts to become marginal. An application where this capability of

TOF-MS is particularly important is when multidimensional protein identification technology (MuDPIT) is used. Mixtures of many proteins (e.g., 100s) are digested and the peptides are loaded onto a strong cation exchange column. Sequential elution with mobile phase of increasing ionic strength fractionates the complex mixture of peptides for separate introduction on a reversed-phase column. IDA is performed on the reverse-phase peptide separations and in a typical run over several hours as many as 5000 individual MS/MS spectra can be recorded for automatic interpretation of amino acid sequence and database searching to identify the original proteins. Hundreds of proteins can be identified in such experiments.

In addition to product ion spectra, MS/MS systems are capable of modes to show precursors of a specific product ion or to screen for a constant neutral loss or presence of a product/precursor pair. These modes involve scanning both MS(1) and MS(2) or not scanning MS(2) so the duty cycle advantage is not as significant as in the product scan mode.

As mentioned above, MALDI oa-TOF-MS is feasible and the hybrid quadrupole TOF systems are available to provide the additional feature of MS/MS. One of the key advantages of MALDI TOF-MS is that it can provide a simple spectrum that reveals the molecular ions from a complex mixture. This is a common experiment in protein analysis, where a list of peptide masses that is referred to as a peptide mass fingerprint (PMF) is generated after digestion of an isolated whole protein with a proteolytic reagent (see Figure 4). The PMF is compared to databases of

predicted proteolysis products when a particular enzyme or reagent acts on a known protein sequence. MS/MS offers the ability to *de novo* sequence individual peptide ions and this can greatly increase the success of protein identification. The combination of rapid acquisition of the PMF followed by MS/MS if it is required is powerful.

MALDI produces predominantly singly charged molecular ions  $[M + H]^+$  as precursors for MS/MS. This is a disadvantage compared to ESI MS/MS where abundant doubly charged ions  $[M + 2H]^{2+}$  are typical. These tend to fragment in CID to give a more extensive sequence of ions than singly charged precursors.

### MALDI TOF/TOF Instruments

MS/MS spectra of MALDI ions can be obtained in a tandem TOF/TOF instrument. These instruments are essentially a linear TOF followed by a reflecting TOF MS system. The first TOF focuses MALDI ions into a collision cell. An ion gate in the first stage allows a specific precursor or all ions to pass into MS(1). Fragments of collisions (if desired) are passed to MS(2), which records the product ion spectrum. This mass spectrometer utilizes a high proportion of the ions generated in the source. It also subjects precursor ions to much higher collision energies than they would experience in a hybrid quadrupole TOF-MS system. As such there is a greater likelihood of seeing sufficient sequence ions even though the precursors are only singly charged. On the other hand, there is a tendency for CID spectra to be complicated by

fragmentation of the amino acid residues. This can make interpretation difficult. Despite these limitations the system can be automated to analyze very large numbers of samples in IDA mode and well suited for high throughput protein analysis laboratories.

### GC-MS, Electron Ionization, and Field Ionization

TOF-MS has long been promising to facilitate faster GC-MS. This is a growing area though not as fast as for the bioanalytical applications. The advantage of high-speed GC/MS is countered by the loss of sample capacity when using narrow-bore capillary GC.

Notwithstanding this, there are commercial GC-TOF-MS instruments and most of these are based on the oa-TOF-MS principle. The most successful of these offer the key advantages of better sensitivity in the full scan mode (oa-TOF-MS has a higher duty cycle than a scanning MS) and much greater mass accuracy than for other small mass spectrometers. Mass accuracy of 10 ppm or better is possible with oa-TOF-MS and this allows sufficient significant figures in ion mass to deduce the empirical formula. This could otherwise be achieved only with much larger and more expensive double-focusing magnetic mass spectrometer or Fourier transform mass spectrometers.

An interesting development in GC-TOF-MS is its combination with field ionization (FI). Many compounds of interest do not provide good molecular weight information by normal ionization methods,

whereas FI produces primarily molecular ions. The mass and full spectrum sensitivity of oa-TOF-MS combines well with FI as does the ability of TOF-MS to provide signal averaged spectra faithfully even when the ionization process is unsteady. RMS mass errors of less than 1.5 amu are attainable for small molecules ( $m/z < 400$ ).

Another GC-MS application of considerable potential is with comprehensive gas chromatography (GC  $\times$  GC). A short fast column follows a longer standard column and fractions eluting from the first column are trapped and periodically released into the second (fast) column. The second column has a stationary phase that is different from that of the first so that there is a tendency for the compounds that co-elute from the first column to separate in the second column. GC  $\times$  GC requires full scan spectra for separations less than 20–30 s and TOF-MS is ideal for this speed of analysis.

### Inductively Coupled Plasma Ionization TOF-MS

The coupling of TOF-MS to the inductively coupled plasma (ICP) ion source is challenging because of the large velocity spreads present in the intense ion beam. Notwithstanding this, the advantage of full spectrum sensitivity and the ability to perform full element analysis with transient inlet systems such as laser ablation and chromatography has provided a considerable driving force for ICP-TOF-MS. An additional advantage is a considerably improved precision of isotope ratios in the TOF systems compared

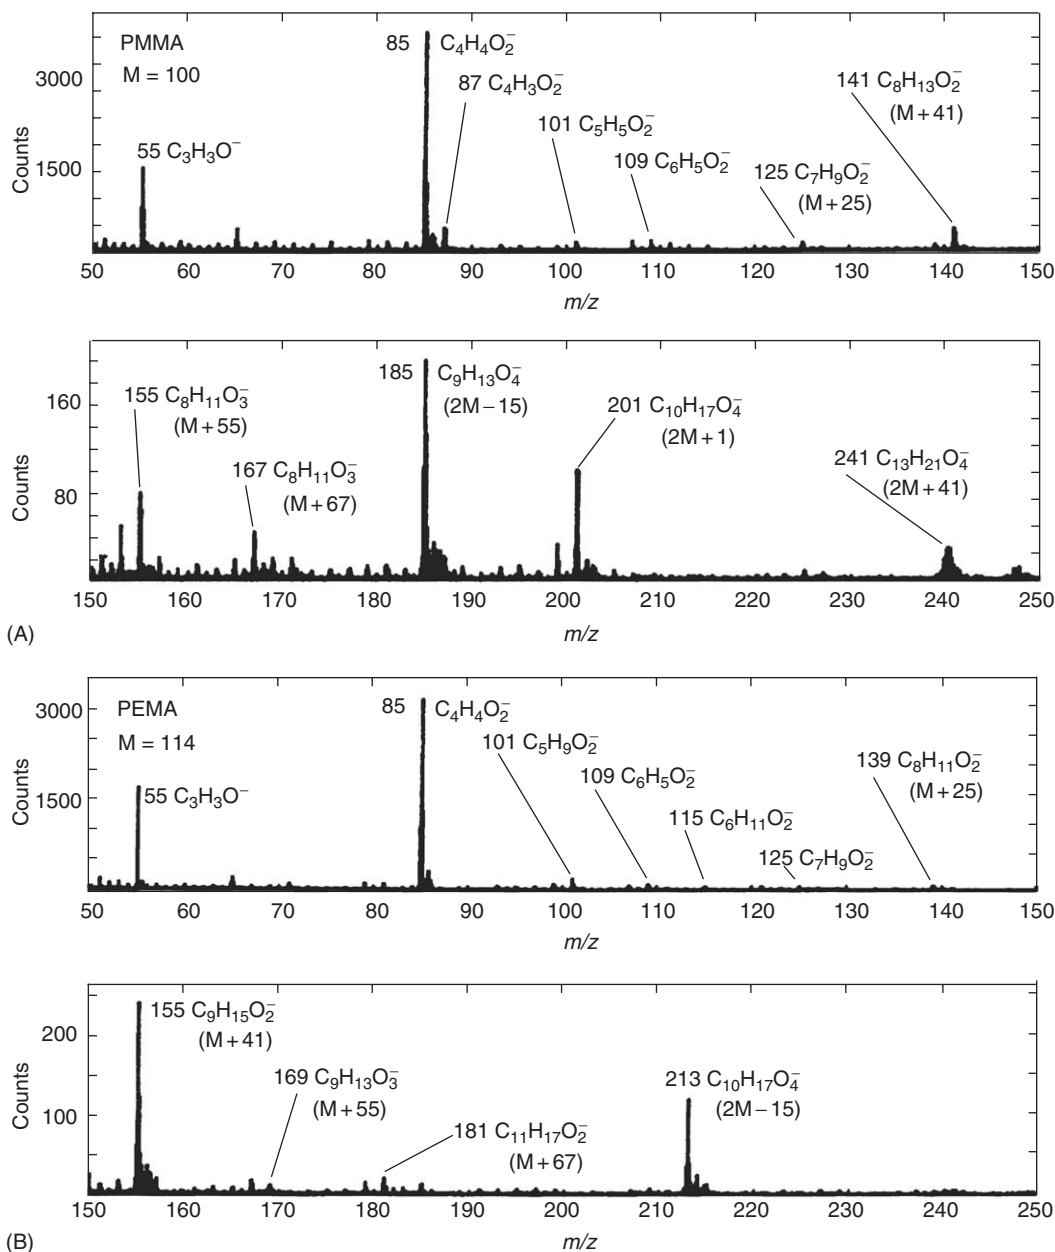

**Figure 8** A 0–100  $m/z$  mass spectrum of a particle inclusion in a polymer matrix obtained from an LIMA (Laser Ionization Mass Analyzer, Cambridge Mass Spectrometry, UK) instrument. From the LIMA spectrum it is suspected that these inclusions are paint-coated rust particles. Inset micrograph shows inclusions typical of those analyzed.

to quadrupole and magnetic mass spectrometers. The reason for this is that the latter instruments are slow scanning and the conditions in the source can change considerably as the scan proceeds from one isotope to another. TOF, on the other hand, samples ions from the plasma almost simultaneously. Two commercial ICP-TOF-MS instruments have recently emerged. One uses an axial (ion-bunching) geometry while the other is based on oa-TOF-MS. Both give resolving powers of  $\sim 2000$  FWHM and they deliver the promised speed of analysis.

### Surface Analysis

TOF-MS has played an important role in analyzing ions generated from surfaces for the purpose of characterizing the chemical composition of the surface or bulk analysis of small inclusions at the surface of a solid. This role extends back well before TOF became famous in bioanalytical chemistry. Ions are most typically generated from surfaces by irradiation with a laser beam or an ion beam.
